A CRITICAL APPROACH TO MODELLING OF DEPTH DISTRIBUTIONS AND TRANSPORT OF RADIONUCLIDES IN SOILS AND SEDIMENTS AND RELATED PROBLEMS

Roland Haas

## Preface

This internet-publication centres around the vertical transport of radionuclides in soils and sediments. It's approach can be summarized as follows: The basic data are taken from publications of many different authors. These authors treated their measured values in quite different ways, ranging from very simple to highly sophisticated methods. Time series analysis as a means to forecast the vertical transport of radionuclides in soils and sediments has been applied only in a few cases. In this publication, however, time series analysis, based on the time dependant Weibull-distribution, is generally applied. The results achieved are compared with the results from models widely published in the literature. Many tables and figures show that the new method is generally applicable. Such a broad presentation would have been impossible in a journal article, and last but not least an internet-publication allows an unbiased presentation of this new forecasting method.

Summary. The main goal of this publication is the development and application of an empirical method, which allows to forecast the transport of radionuclides in soils ad sediments. The calculations are based on data published in the literature. 10 case studies, comprising 30 time series, deal with the transport of ${ }^{134} \mathrm{Cs},{ }^{137} \mathrm{Cs},{ }^{85} \mathrm{Sr},{ }^{90} \mathrm{Sr}$, and ${ }^{106} \mathrm{Ru}$. Transport in undisturbed soils and experimental systems like lysimeters and columns in laboratories are dealt with. The soils involved cover a large range of soils, e. g. podsols, cambisols (FAO), and peaty soils. Different speciations are covered, namely ions, aerosols, and fuel particles. Time series analysis centres around the Weibull-distribution. All theoretical models failed to forecast the transport of radionuclides. It can be shown that the parameters D and v , the dispersion coefficient and the advection velocity, appearing in solutions of the advection-dispersion equation (ADE), have no real physical meaning. They are just fitting parameters. The calculation of primary photon fluence rates, caused by ${ }^{137} \mathrm{Cs}$ in the soil, stresses the unreliability of forecasts based on theoretical models.

Kurzfassung. Hauptgegenstand dieser Publikation ist die Entwicklung und Anwendung einer empirischen Methode, die es gestattet, den Transport von Badionukliden in Böden und Sedimenten vorherzusagen. Die Berechnungen stützen sichauf Daten, die in der Literatur bereits veröffentlicht waren. Im Rahmen von 10 Fallstudien, die 30 Zeitreihen umfassen, wird der Transport von ${ }^{134} \mathrm{Cs},{ }^{137} \mathrm{Cs},{ }^{85} \mathrm{Sr},{ }^{99} \mathrm{Sr}$ und ${ }^{106} \mathrm{Ru}$ untersucht. Die Untersuchungen behandeln den Transport in ungestörten Böden und experimentellen Systemen wie Lysimetern und Säulenanordnungen in Laboratorien. Die untersuchten Böden umfassen einen weiten Bereich, z. B. Podsole, Cambisole (FAO) und Torfböden. Weiterhin wird der Transport unterschiedlicher physiko-chemischer Formen wie Ionen, Aerosole und Brennstoffteilchen behandelt. Die Zeitreihenanalyse stützt sich im Kern auf die Weibullverteilung. Alle theoretischen Modelle waren nicht in der Lage, den Transport von Radionukliden vorherzusagen. Es kann nachgewiesen werden, dass die Parameter D/und v, der Dispersionskoeffizient und die Advektionsgeschwindigkeit, die in den Lösungen der Advektions-Dispersions-Gleichung auftreten, keine reale physikalische Bedeutung haben. Sie sind nur Fitting-Parameter. Die Berechnung des primären Photonenflusses, welcher durch ${ }^{137} \mathrm{Cs}$ in Böden verursacht wird, unterstreicht die Unzuverlässigkeit der Vorhersagen, die sich auf theoretische Modelle stützen.

Keywords: ${ }^{134} \mathrm{Cs} /{ }^{137} \mathrm{Cs} /{ }^{85} \mathrm{Sr} /{ }^{99} \mathrm{Sr} /{ }^{106} \mathrm{Ru} /$ Soil / Advection-dispersion equation / Transfer function model / Time dependant Weibull-distribution / Transport / Time series analysis / Primary photon fluence rates

## 1. Introduction

Since the very beginning of the nuclear age artificial radionuclides were released to the atmosphere, and finally they have spread throughout the geosphere. This has caused an additional external and internal radiation exposure. It is therefore quite understandable that nuclear explosions in the atmosphere and especially the Chernobyl accident have led to intensive research in the field of radioecology. Special attention was paid to transport processes in the atmosphere, in soils and sediments, surface waters, fauna, and flora, since the transport of radionuclides finally determines the additional radiation exposure.

Finally, because of their half-lives, only cesium-137 $\left({ }^{137} \mathrm{Cs}\right)$ and strontium- $90\left({ }^{90} \mathrm{Sr}\right)$ cause the
additional radiation exposure. ${ }^{137} \mathrm{Cs}$, a gamma emitter, has a half-life of 30.17 years, and ${ }^{90} \mathrm{Sr}$, a beta emitter, has a half-life of 28.64 years. ${ }^{137} \mathrm{Cs}$ causes as a gamma emitter an external and internal radiation exposure, whereas ${ }^{90} \mathrm{Sr}$ only causes an internal radiation exposure. The internal radiation exposure is, amongst others, caused by the food chain. Since ${ }^{137} \mathrm{Cs}$ is, from the radioecological point of view, more important, it has attracted special attention.

Cesium and potassium are alkali metals, and therefore both of them behave similarly with respect to metabolism and transport in soils and sediments. This similar behaviour affects the internal and external radiation exposure caused by ${ }^{137} \mathrm{Cs}$, since the depth distributions of ${ }^{137} \mathrm{Cs}$ influence its root uptake and the attenuation of its gamma radiation. Strontium and calcium are earth alkali metals, and therefore both of them behave similarly.

Because of the importance of depth distributions of radionuclides in soils and sediments and their time dependence, these problems have been approached by many workers in the field, both by theoretical and empirical models, but because of the problems involved essential questions remained unanswered. It is therefore justified to have a fresh look at the problems involved. All calculations were performed with Mathcad 2000 Professional.

## 2. Modelling of solute transport

### 2.1 Theoretical models

### 2.1.1 Advection-dispersion equation (ADE)

The basic differential equation describing the 1-dimensional transport of a radioactive solute in a porous, macroscopic homogeneous, and sorbing medium is based on the mass balance principle:

$$
\frac{\partial C}{\partial t}=\frac{D}{R} \cdot \frac{\partial^{2} C}{\partial x^{2}}-\frac{v}{R} \cdot \frac{\partial C}{\partial x}-\lambda \cdot C(\mathbf{2}-1)
$$

where
$\mathrm{C}=\mathrm{C}(\mathrm{x}, \mathrm{t})$
x is the depth coordinate in $(\mathrm{cm})$.
$t$ is the time in (a).
C is the concentration in $\left(\mathrm{Bq} \mathrm{cm}^{-3}\right)$.
$D$ is the dispersion coefficient in $\left(\mathrm{cm}^{2} \mathrm{a}^{-1}\right)$.
v is the advection velocity in ( $\mathrm{cm} \mathrm{a}^{-1}$ ).
R is the retardation factor $(-)$.
$\lambda$ is the decay constant in $\left(\mathrm{a}^{-1}\right)$.
A few remarks should indicate that the properties of real soils and sediments differ from the assumptions on which Eq. (2-1) is based. Especially in the case of cesium the Local Equilibrium Assumption (LEA), i. e. the instantaneous sorption equilibrium, is not applicable. R, D, and v are assumed to be constants. This has the advantage that in many cases analytical solutions of Eq. (2-1) can be derived, but the disadvantage is evident: The assumptions differ largely from reality, and this will of course have negative consequences. Haas [1] has treated these problems in detail.

For the complete definition of the transport problem the ADE has to be completed by the appropriate initial and boundary conditions. In the case of transport of radionuclides in soils it is usually assumed that for $\mathrm{t}<0$ there is no radionuclide in question, e. g. ${ }^{137} \mathrm{Cs}$, in the soil. This
assumption is of course mostly wrong, since ${ }^{137} \mathrm{Cs}$ was deposited over many years. But because of a lack of information about the initial condition, and also for other reasons, there is no other way out of this problem. Also the choice of the correct boundary condition for $\mathrm{x}=0$ causes problems. In principal there are two types of boundary conditions: the flux-type and the concentration-type boundary condition. A detailed discussion would show that both types are simplifications of the real deposition conditions. Since the concentration-type boundary condition leads to simpler solutions, it is preferred. In the case of a plane source the solution of Eq. (2-1) is [2]

$$
\begin{equation*}
C(x, t)=\frac{M_{0} \exp (-\lambda t)}{\sqrt{\pi D t}} \cdot \exp \left[\frac{-(x-v t)^{2}}{4 D t}\right]-\frac{v}{2 D} \cdot \exp \left(\frac{v}{D} x\right) \cdot \operatorname{erfc}\left[\frac{x+v t}{2 \sqrt{D t}}\right] \tag{2-2}
\end{equation*}
$$

$M_{0}\left(\mathrm{~Bq} \mathrm{~cm}^{-2}\right)$ is the total specific inventory for $t=0$. For practical reasons $D / R$ and $v / R$ in Eq. (2-1) are replaced by the apparent dispersion coefficient resp. the apparent advection velocity. For the sake of simplicity the symbols D and v are also used for the apparent quantities. erfc denotes the complementary error function. It can be shown that only the flux-type boundary condition leads under all circumstances to a correct mass balance, i. e. the mass conservation law is not violated.

There is an elegant way out of this problem. One can find a function $C(x, t)$, which does not violate the mass conservation law in the case of a plane source, but $\mathrm{C}(\mathrm{x}, \mathrm{t})$ is not a real solution of Eq. (2-1). This function

$$
\begin{align*}
& C(x, t)=\frac{M_{0} \exp (-\lambda t)}{2 \sqrt{\pi D t}} \cdot\left[\exp \left[\frac{-(x-v t)^{2}}{4 D t}\right]+\exp \left[\frac{-(x+v t)^{2}}{4 D t}\right]\right]  \tag{2-3}\\
& \text { has been studied in detail by Haas [1] and is referred to as quasi-solution. }
\end{align*}
$$

### 2.1.2 Transfer function model

Assuming convective-stochastic transport [3, 4], one gets

$$
\begin{equation*}
C(x, t)=\frac{M_{0} \exp (-\lambda t)}{\sigma \sqrt{2 \pi}} \cdot \frac{1}{x} \cdot \exp \left[\frac{\left(\ln \left(\frac{\tau}{t} \cdot x\right)-\mu\right)^{2}}{-2 \sigma^{2}}\right] \tag{2-4}
\end{equation*}
$$

The radionuclide was applied to the soil surface at $t=0$, and after $\tau$ (a) soil samples were taken. $\sigma(-)$ and $\mu(-)$ are the parameters of this lognormal distribution. They are determined by means of curve fitting. $\tau$ is the reference time, and $\tau / \mathrm{t}$ is the scaling factor. If the underlying scaling law is correct, it is possible to calculate $\mathrm{C}(\mathrm{x}, \mathrm{t})$ for each point of time.

### 2.2 Empirical models

### 2.2.1 Background

Since the early days of radioecology depth distributions of radionuclides were often approximated by simple exponential functions [5-7], but also after the development of highly sophisticated theoretical transport models certain workers in the field [8,9] used the simple exponential function as a basis for time series analysis, i. e. as a basis to estimate the development of depth distributions of radionuclides in soils and sediments. It's evident that they did not want to rely on models, which are based on assumptions, which are rather questionable. Extensive tests after the Chernobyl accident have proved that $D$ and $v$ in Eq. (2-3) are not at all constants, in contrary, they varied over a period of 8 (a) dramatically, and because of fitting problems one even had to use a superposition of Eq. (2-3), i. e. one had to assume a slow and a fast ${ }^{137} \mathrm{Cs}$ component [10].

In some special cases it might be justified to use a simple exponential function to model depth distributions of radionuclides in soils and sediments, but in most cases a more general approach is needed. This more general approach is based on the Weibull-distribution.

### 2.2.2 Weibull-distribution

The Weibull-distribution, applied to depth distributions of radionuclides in soils and sediments [1], can be written as follows:
$C(x)=M_{0} \cdot \exp (-\lambda t) \cdot a \cdot n \cdot x^{n-1} \cdot \exp \left(-a x^{n}\right)(2-5)$
where

$$
M_{0} \cdot \exp (-\lambda t)=M_{\infty}(2-6)
$$

$\mathrm{M}_{\infty}$ is thus the total specific inventory for $\mathrm{t} \geq 0$. $\mathrm{a}\left(\mathrm{cm}^{-\mathrm{n}}\right)$ and $\mathrm{n}(-)$ are the Weibull-parameters.
a, $n>0$
One can easily show that

Eq. (2-5) is thus in line with the basic requirement: It does not violate the mass conservation law. For $\mathrm{n}=1$ Eq. (2-5) is the simple exponential function.

It's a general habit to use $C(x, t)$ resp. $C(x)$ as fitting equation for the estimation of the parameters involved. A better approach is the integral method used by Haas [1, 11]:
$M(x, t)=\int_{0}^{x} C(y, t) d y(\mathbf{2 - 8})$
y is the integration variable. The integral method is adapted to the sampling method, i. e. to stacked samples. The use of $M(x, t)$ resp. $M(x)$ instead of $C(x, t)$ resp. $C(x)$ avoids using the difference quotient to approximate the differential quotient.

Taking into account Eq. (2-5) and (2-6), Eq. (2-8) leads to the cumulative Weibull-distribution

$$
M(x)=M_{\infty} \cdot\left[1-\exp \left(-a x^{n}\right)\right](\mathbf{2 - 9 )}
$$

Normally only a and $n$ are considered to be the fitting parameters, but sometimes it can be cumbersome and questionable to determine $\mathrm{M}_{\infty}$ experimentally. In such cases also $\mathrm{M}_{\infty}$ is considered to be a fitting parameter. Extensive tests have shown that Eq. (2-9) is an excellent fitting equation and extrapolation function [1].

The quality of a fit is characterized by the coefficient of determination $r^{2}$ [12]. $r^{2}$, in (\%), is defined as

where $\mathrm{F}_{\mathrm{i}}$ denotes the function's value, $\mathrm{M}_{\mathrm{i}}$ the corresponding cumulative specific inventory, and $\overline{\mathrm{M}}$ the arithmetical mean of the $\mathrm{M}_{\mathrm{i}}$. By definition is $0 \leq \mathrm{r}^{2} \leq 100$.

In [1] details about fits with Eq. (2-9) are given. For 46 fits the arithmetical mean of the coefficient of determination is 99.87 (\%), and the standard deviation is only 0.21 (\%). The corresponding figures for the fits with Eq. (2-3) are 86.20 (\%) and 19.10 (\%). A comparison of both sets of figures indicates the superiority of Eq. (2-9). For time series analysis it is of great importance that the standard deviation is very small, i. e. that the respective fitting equation is generally reliable.

For comparisons it is better to use the quantities $\mathrm{M}(\mathrm{x}) / \mathrm{M}_{\infty}(-)$ and $\mathrm{C}(\mathrm{x}) / \mathrm{M}_{\infty}\left(\mathrm{cm}^{-1}\right)$ instead of $\mathrm{M}(\mathrm{x})\left(\mathrm{Bq} \mathrm{cm}^{-2}\right)$ and $\mathrm{C}(\mathrm{x})\left(\mathrm{Bq} \mathrm{cm}^{-3}\right)$. For the sake of simplicity the former symbols $\mathrm{M}(\mathrm{x})$ and $\mathrm{C}(\mathrm{x})$ are also used for the new quantities.

Haas [11] has demonstrated that it is possible to model the Weibull-parameters a and n in function of the time $t$, i. e. it is possible to arrive empirically at the time dependant Weibulldistributions
$M(x, t)=1-\exp \left(-a(t) \cdot x^{n(t)}\right)(\mathbf{2 - 1 1})$
$C(x, t)=a(t) \cdot n(t) \cdot x^{n(t)-1} \cdot \exp \left(-a(t) \cdot x^{n(t)}\right)(\mathbf{2 - 1 2})$
It is also possible to calculate further quantities depending on $a(t)$ and $n(t)$. An interesting distribution is the percentage distribution $\mathrm{p}(\mathrm{x}, \mathrm{t})$, which results from Eq. $(2-11)$.
$p(x, t)=100 \cdot \exp \left(-a(t) \cdot x^{n(t)}\right)$
p denotes the percentage of the total speeific inventory below x .
The nominal root depth of permanent pastures is $10(\mathrm{~cm})$. The retention of a radionuclide in the upper $10(\mathrm{~cm})$ in $(\%), \mathrm{R}(10, \mathrm{t})$, is therefore an interesting quantity.
$R(10, t)=100 \cdot\left[1-\exp \left(-a(t) \cdot 10^{n(t)}\right)\right][(2-14)$
A further interesting quantity is the penetration depth $\mathrm{P}_{\mathrm{p}}(\mathrm{t})(\mathrm{cm})$. It is the thickness of the top layer, which contains $\mathrm{p}(\%)$ of the radionuclide.

$$
P_{p}(t)=\left[-\frac{1}{a(t)} \cdot \ln \left(1-\frac{p}{100}\right)\right]^{\frac{1}{n(t)}}(\mathbf{2 - 1 5 )}
$$

The treatment of 10 case studies, based on [7-9,13-19], comprising 30 time series, exhibits that the following functions are extremely useful for the solution of different fitting problems involved in time series analysis:
$f_{1}(t)=b \cdot\left[1-\exp \left(-c \cdot t^{m}\right)\right]$
$f_{2}(t)=b \cdot\left[1-\exp \left(-c \cdot t^{m}\right)\right]+d \mathbf{( 2 - 1 7 )}$
$f_{3}(t)=\frac{b}{t^{k}} \cdot \exp \left[-c \cdot\left[\sqrt{(\ln (t)-d)^{2}}\right]^{m}\right]$
$f_{4}(t)=\frac{b}{t^{k}} \cdot \exp \left[-c \cdot\left[\sqrt{(\ln (t)-d)^{2}}\right]^{m}\right]+f(\mathbf{2 - 1 9})$

$$
\begin{align*}
& f_{5}(t)=b \cdot\left[\exp \left[-c \cdot\left[\sqrt{(t-d)^{2}}\right]^{m}\right]+\exp \left[-c \cdot(t+d)^{m}\right]\right](\mathbf{2 - 2 0}  \tag{2-20}\\
& f_{6}(t)=b \cdot\left[\exp \left[-c \cdot\left[\sqrt{(t-d)^{2}}\right]^{m}\right]+\exp \left[-c \cdot(t+d)^{m}\right]\right]+f \tag{2-21}
\end{align*}
$$

$\mathrm{b}, \mathrm{c}, \mathrm{d}, \mathrm{f}, \mathrm{k}$, and m are the fitting parameters. Eq. (2-16) and (2-17) are based on the cumulative Weibull-distribution, whereas Eq. (2-18) and (2-19) resp. (2-20) and (2-21) are based on the socalled loggamma distribution [1] resp. gamma-2-distribution [1].

For the purpose of prognoses the functions $a(t)$ and $n(t)$, resulting from the first fits, have to be adapted in a certain way. Extensive tests have shown that adaptation to $\mathrm{x}_{\mathrm{s}}(\mathrm{t})$, the fitting curve of the centres of gravity of the depth distributions, is the most appropriate adaptation method. The best fitting equation for $\mathrm{x}_{\mathrm{s}}(\mathrm{t})$ is Eq. (2-16). The centre of gravity of a depth distribution is

$$
x_{s}=\int_{0}^{\infty} x \cdot C(x) d x(\mathbf{2 - 2 2})
$$

If $C(x)$ represents the Weibull-distribution, one gets
$x_{s}=\frac{\Gamma\left(\frac{1}{n}\right)}{n \cdot a^{\left(\frac{1}{n}\right)}}$ (2-23)

where $\Gamma$ denotes the gamma function. After the adaptation process the graph, represented by Eq. (2-24), should allow to match the graph of $\mathrm{x}_{\mathrm{s}}(\mathrm{t})$, represented by Eq. (2-16).
$x_{s}(t)=\frac{\Gamma\left(\frac{1}{n(t)}\right)}{n(t) \cdot a(t)\left(\frac{1}{n(t)}\right)}$
The modified functions are based on the construction of a 2-dimensional nest of intervals for different points of time. The construction of such a 2-dimensional nest of intervals for a certain point of time $t_{p}$, for which a prognosis is wanted, can be described as follows:
$a\left(t_{p}\right)$, resulting from the first fit, is considered to be correct, and $n\left(t_{p}\right)$, resulting from the first fit, is adjusted by method of trial and error, until $\mathrm{x}_{\mathrm{s}}$ (Eq. (2-23)) equals $\mathrm{x}_{\mathrm{s}}\left(\mathrm{t}_{\mathrm{p}}\right)$ (Eq. (2-16)). The result is called $\mathrm{n}_{\mathrm{r}}$.
$\mathrm{n}\left(\mathrm{t}_{\mathrm{p}}\right)$, resulting from the first fit, is considered to be correct, and $\mathrm{a}\left(\mathrm{t}_{\mathrm{p}}\right)$, resulting from the first fit,
is adjusted by method of trial and error, until $\mathrm{x}_{\mathrm{s}}$ (Eq. (2-23)) equals $\mathrm{x}_{\mathrm{s}}\left(\mathrm{t}_{\mathrm{p}}\right)$ (Eq. (2-16)). The result is called $\mathrm{a}_{\mathrm{r}}$.
The arithmetical means
$a_{m}=\frac{a\left(t_{p}\right)+a_{r}}{2}$
$n_{m}=\frac{n\left(t_{p}\right)+n_{r}}{2}$
are first approximations of the correct a - and n -value. $\mathrm{a}_{\mathrm{m}}$ and $\mathrm{n}_{\mathrm{m}}$ are the basis for a second approximation. Higher order approximations can be calculated in the same way. The number of approximations required ranges from 2 to 4 , depending on how much $\mathrm{x}_{\mathrm{s}}$ (Eq. (2-23)) deviates from $x_{s}\left(t_{p}\right)($ Eq. (2-16)). The result of this approximation procedure depends on the starting point $\left(a\left(t_{p}\right), n\left(t_{p}\right)\right)$ in the $a, n-p l a n e$, but it's practical influence is limited to cases of an extreme relative deviation. The consequence of this fact is the following one: The fitting equations for the first fits $a(t)$ and $n(t)$ must be chosen in such a way that the relative deviations mentioned above are kept as small as possible.

The new sets of a - and n -values are fitted again. These second fits $\mathrm{a}(\mathrm{t})$ and $\mathrm{n}(\mathrm{t})$ are the basis for prognoses.

A prognosis should be complemented by an error estimation. The method applied is a simple, intuitive procedure. It can be described as follows: The $\mathrm{x}_{\mathrm{s}}$-fit is described by $\mathrm{x}_{\mathrm{s}}(\mathrm{t})$ (Eq. (2-16)). The data points, scattered around $\mathrm{x}_{\mathrm{s}}(\mathrm{t})$ (Eq. (2-16)), can be confined in a sector. The upper limit of this sector is $c_{u} X_{s}(t)$, and the lower limit of this sector is $c_{1} x_{s}(t)$. The constants $c_{u}$ and $c_{1}$ are determined by method of trial and error. It is assumed that this sector is also representative for the time interval $\left(t_{s}, t_{\mathrm{p}}\right)$. $\mathrm{t}_{\mathrm{s}}$ is the point of time of the last sampling. This method will be referred to as sector-method.

## 3. Sampling

A critical study of the literature on depth distributions and transport of radionuclides in soils and sediments gives the impression that workers in the field are not always fully aware of the implications of sampling. Sampling should be seen from the scientific and economic point of view. First of all the aims of the research project must be clearly identified, and thereafter an adequate sampling strategy has to be elaborated, taking into account that besides sampling all subsequent work involved influences the overall economy of the research project. In other words, one has to minimize the costs for a maximum of high quality information.

Let's assume the aim of the research project is the following one: Estimation of the long term external radiation exposure caused by ${ }^{137} \mathrm{Cs}$ in the soil of a virtually flat permanent pasture. First of all, sampling should be representative. Representative sampling must take into account the area of the site and the variability of the relevant soil properties. Since it is impossible to base a prognosis of the development of a depth distribution on a single sampling, it is evident that one has to employ time series analysis [11]. This in turn necessitates that samples, taken at different points of time, must be representative for a narrow area. Then the question arises, how this can be achieved. Experience has shown that total specific inventories and depth distributions can
change dramatically even within a narrow area [1]. In order to cope with these problems, a certain number of sampling points has to be chosen. Gamma spectrometric measurements, followed by a statistical analysis, will then show, whether the number of sampling points is sufficient or has to be increased. This strategy finally leads to representative sampling and representative data for a certain point of time. If it is also intended to study, whether the total specific inventories within a certain area belong to a single population or not, a statistical method, e. g. the Kruskal-Wallistest [1, 12], has to be applied. In the case of the Kruskal-Wallis-test the number of sampling points within a sub-area must be at least 5 .

Let's assume that sampling will be performed by means of frames and scrapers. Then it is possible to keep the errors involved within narrow limits, provided the right measures are taken [1]. In the case of ${ }^{137} \mathrm{Cs}$ it is mostly sufficient to sample to a depth of $20(\mathrm{~cm})$. For ${ }^{90} \mathrm{Sr}$ the sampling depth could be greater. It's in any way not necessary to catch $\mathrm{M}_{\infty}$ completely, since Eq. $(2-9)$ is an excellent extrapolation function. Experience has shown that in the case of stacked samples the optimum number of layers is 5 [1]. Certain workers in the field have sampled $1(\mathrm{~cm})$ layers. This is not at all necessary, it's in fact a waste of time and money, i. e. not economic. The thickness of the layers has to be adapted to the depth distribution of the radionuclide in question, i. e. for greater depths the thickness of the layer can be increased. This measure has no negative effects.

Sampling of the top layer requires special attention. Because of the roots and the micro-relief it is advised to sample a layer with a nominal thickness of $3(\mathrm{~cm})$. The effective thicknesses mentioned in [1] range from $1.9(\mathrm{~cm})$ to $3.5(\mathrm{~cm})$. These figures also indicate that $\mathrm{x}=0$, i. e. the soil surface, is a mathematical idealization of the physical reality.

## 4. Application of models

It is not sufficient to establish a theory or method, but it must be complemented by extensive testing in order to find out its limitations. To the knowledge of the author of this paper Eq. (2-2), (2-3), and (2-4) were only used as fitting equations for depth profiles, but their predictive power was, until the work of Haas [11], an open question, i. e. the already existing experimental results were not used.

Haas [11] has extensively tested the predictive power of his empirical method, which is based on the time dependant Weibull-distribution. This paper deals with the transport of ${ }^{134} \mathrm{Cs},{ }^{137} \mathrm{Cs}$, ${ }^{85} \mathrm{Sr},{ }^{90} \mathrm{Sr}$, and ${ }^{106} \mathrm{Ru}$. Transport in undisturbed soils and experimental systems like lysimeters and columns in laboratories are dealt with. The soils involved cover a large range of soils, e. g. podsols, cambisols (FAO), and peaty soils. Different speciations are covered, namely ions, aerosols, and fuel particles.

## 5. Calculation of primary photon fluence rates caused by gamma emitters in soils and sediments

The theory has been developed by Finck [20]. The geometry used for the calculation of primary photon fluence rates is based on 2 semi-infinite half-spaces of soil and air, which are separated by an infinite, plane soil surface. In this geometry a photon source element is contained in a volume element dV of soil at a vertical depth x below the soil surface. Suppose that the photon source distribution is represented by $C(x, r, \eta)$, where $x$ denotes the depth below the soil surface, $r$ the lateral distance, and $\eta$ the azimuthal angle, then the photon emission from the volume
element is $C(x, r, \eta) d V$. The primary photon fluence rate $d \Phi_{p}$ at the position of a hypothetical detector at height $h$ above the ground and at the distance R from this volume element can be expressed as

$$
\begin{equation*}
d \Phi_{p}=\frac{C(x, r, \eta) \cdot d V \cdot \exp \left[-\mu_{s} \cdot(R-h \cdot \sec \theta)-\mu_{a} \cdot h \cdot \sec \theta\right]}{4 \cdot \pi \cdot R^{2}} \tag{5-1}
\end{equation*}
$$

where $\mu_{\mathrm{s}}$ and $\mu_{\mathrm{a}}$ are the linear attenuation coefficients in soil resp. air, and $\theta$ denotes the angle between the normal to the air-soil interface and the direction of the primary photons at the position of the detector. Since
$d V=r \cdot R \cdot d \boldsymbol{\eta} \cdot d R \cdot d \boldsymbol{\theta} \mathbf{( 5 - 2 )}$
and
$\sin \theta=\frac{r}{R}(5-3)$
$\Phi_{p}=\int_{0}^{\frac{\pi}{2}} \int_{h \sec \theta}^{\infty} \int_{0}^{2 \pi} \frac{C(x, r, \eta) \cdot \sin \boldsymbol{\theta} \cdot \exp \left[-\mu_{s}(R-h \sec \theta)-\mu_{a} h \sec \boldsymbol{\theta}\right]}{4 \pi} d \eta d R d \boldsymbol{\theta}(\mathbf{5 - 4 )}$
If the photon source distribution does not depend on the azimuthal angle $\eta$
$\Phi_{p}=\int_{0}^{\frac{\pi}{2}} \int_{h \sec \theta}^{\infty} \frac{C(x, r) \cdot \sin (\theta) \cdot \exp \left[-\mu_{s}(R-h \sec \theta)-\mu_{a} h \sec \theta\right]}{2} d R d \boldsymbol{\theta}(\mathbf{5 - 5})$
If, in addition, the photon source distribution depends only on the depth x , one gets

$$
\Phi_{p}=\int_{0}^{\frac{\pi}{2}} \int_{h \sec \theta}^{\infty} \frac{C(x) \cdot \sin (\boldsymbol{\theta}) \cdot \exp \left[-\mu_{s}(R-h \sec \boldsymbol{\theta})-\mu_{a} h \sec \theta\right]}{2} d R d \boldsymbol{\theta}(\mathbf{5 - 6})
$$

A general solution of the integral (5-6) for any $C(x)$ is not possible, but also a numerical evaluation of this integral is impossible, since $\mathrm{h} \sec \theta$ approaches $\infty$ if $\theta$ approaches $\pi / 2$. But for $h=0$ a numerical evaluation of the integral (5-6) is possible for any $C(x)$. If $h=0$

$$
\Phi_{p}=\int_{0}^{\frac{\pi}{2}} \int_{0}^{\infty} \frac{C(x) \cdot \sin (\boldsymbol{\theta}) \cdot \exp \left(-\mu_{s} R\right)}{2} d R d \boldsymbol{\theta}^{(5-7)}
$$

The argument of $\mathrm{C}(\mathrm{x})$ has to be expressed in terms of the variables R and $\theta$ :
$x=R \cdot \cos \boldsymbol{\theta}(5-8)$
Normally the position of the detector is $1(\mathrm{~m})$ above the ground. Model calculations for a uniform source distribution indicate that the difference between the primary photon fluence rates for $\mathrm{h}=0$ and $\mathrm{h}=1(\mathrm{~m})$ is negligible.

For a decay energy of $661.6(\mathrm{keV})\left({ }^{137} \mathrm{Cs}\right)$ and a soil density of $1.6\left(\mathrm{~g} \mathrm{~cm}^{-3}\right)$ the linear attenuation coefficient $\mu_{\mathrm{s}}=0.125152\left(\mathrm{~cm}^{-1}\right)$. Finck [20] has based his calculations on the assumption that the composition of soil by weight is as follows:55.8 (\%) O, 31.5 (\%) Si, 7.1 (\%) $\mathrm{Al}, 3.2$ (\%) Fe, 1.3 (\%) C, and 1.1 (\%) H.

## 6. Case studies

### 6.1 Case study 1

Case study 1 is based on [13]. The experiments were carried out by means of open-air lysimeters, fabricated from polyethylene. They had a net cross section of about $1\left(\mathrm{~m}^{2}\right)$ and a volume of about $0.5\left(\mathrm{~m}^{3}\right)$. The walls were designed to minimize the influence of weather conditions. The soils involved are a podsol and a cambisol. ${ }^{137} \mathrm{Cs}$ was applied as chloride, and ${ }^{90} \mathrm{Sr}$ was applied as nitrate, in both cases $37(\mathrm{MBq})$, carrier-free. The radionuclides were homogeneously distributed in the top layer with a thickness of $1(\mathrm{~cm})$. The surfaces were covered with grass. Stacked samples were taken in spring and autumn by means of a Pürckhauer-Bohrstock.
The data in Table 6.1-1 to 6.1-4 are based on Fig. 4 and 5 of [13]. They were gained with high precision by means of the digitizing program WinDig 2.5 (© D. Lovy, Geneva).These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.1-1 to 6.1-4 with

$$
M(x)=1-\exp \left(-a x^{n}\right)(6-1)
$$

leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.1-5 to 6.1-8.
Table 6.1-9 contains the Weibull-parameters a, n, which are based on 2-dimensional nests of intervals. Fig. 6.1-1 resp. 6.1-2 show the first and second fits of a resp. n for time series 1. Fig. 6.1-3 demonstrates the sector-method in the case of time series 1, and Table 6.1-10 contains the corresponding figures. Fig. 6.1-4 demonstrates the almost perfect matching of the centres of gravity and of the penetration depths in the case of time series 1 . Table 6.1-11 and 6.1-12 contain the relevant fitting results for time series 1 to 4 .
Fitting results can be sometimes improved, if the basic fitting equation, i. e. Eq. (2-16) to (2-21), is multiplied by
$f_{7}(t)=\exp [\alpha \cdot(t-\beta)] \cdot t^{\gamma}(6-2)$
$\beta$ and $\gamma$ are mostly 0 . Eq. (6-2) can be applied in different ways: $\alpha, \beta$ and $\gamma$ are

- real fitting parameters.
- calculated by method of trial and error in the framework of the fitting procedure.
- calculated by method of trial and error after the fitting procedure, but this option should be restricted to very small adjustments.
Fig. 6.1-5 exhibits the relative concentrations and Fig. 6.1-6 the inventories below $x$ (\%), in both cases for different points of time for time series 1, and Fig. 6.1-7 demonstrates for time series 1 the relative concentrations after 50 (a), resulting from different models. It's obvious that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils. Table 6.1-13 proves that D and v have no real physical meaning; they are just fitting parameters. The reason for the oscillations near $\mathrm{x}=30(\mathrm{~cm})$ is unknown, but it is evident that they are physically meaningless. The integral over the concentration C (solution ADE, a-profile, $(0, \infty)$ ) equals 1.597. This violation of the mass conservation law is a consequence of the concentration-type boundary condition.
Table 6.1-14 contains the primary photon fluence rates for different models for time series 1, and Table 6.1-15 resp. 6.1-16 contain the fitting results concerning primary photon fluence rates resp. integrated primary photon fluence rates for different models for time series 1. Fig. 6.1-8 and 6.1-9 demonstrate clearly that theoretical models are completely unreliable.

Time series 2 is characterized by Fig. 6.1-10 to 6.1-13. Most comments concerning time series 1 are also applicable to time series 2, butp1(x) in Fig. 6.1-12 shows a very small disturbance, since it intersects $\mathrm{p} 2(\mathrm{x})$ etc. The integral over the concentration C (solution ADE, a-profile, $(0, \infty)$ ) equals this time 2 , i.e., the mass conservation law is again violated.
Time series 3 causes some difficulties. This is due to the steep decrease of $a(t)$, but by means of special adaptations the problems are solvable. Fig. 6.1-14 proves this. Fig. 6.1-14, 6.1-15, and 6.1-16 demonstrate the different behaviour of ${ }^{90} \mathrm{Sr}$. The integral over the concentration C (solution ADE, 1-profile, $(0, \infty)$ ) equals again 2. Fig. 6.1-17 shows that the mass conservation law is again violated. Fig. 6.1-18 and 6.1-19 demonstrate the regular decrease of the relative concentration maxima.
Fig. 6.1-20 to 6.1-23 indicate the similarities between time series 3 and 4. The comments concerning the oscillations, this time near $x=100(\mathrm{~cm})$, are the same as in the case of time series 1. The mass conservation law is again violated. The integral over the concentration C (solution ADE, 1-profile, $(0, \infty)$ ) equals this time 1.133 .
Fig. 6.1-24 demonstrates by means of the retention in the upper $10(\mathrm{~cm})$ the quite different behaviour of ${ }^{137} \mathrm{Cs}$ and ${ }^{90} \mathrm{Sr}$.

### 6.2 Case study 2

Case study 2 is based on [14]. The experiments concerned are column experiments with field soils. Undisturbed soil columns were obtained by slowly pressing $100(\mathrm{~cm})$ long polyvinyl chloride (PVC) tubes with a diameter of $30(\mathrm{~cm})$, having sharp edges on the front, into the soil. Case study 2 deals with a podsol, taken near Gorleben, a small town in northwest Germany. In the laboratory $5(\mathrm{~cm})$ of the soil at the bottom of the column was replaced by a filter of coarse, purified sand ( $1(\mathrm{~mm}$ ) diameter) for better drainage. The column was mounted on a PVC plate, having a small hole in the middle for the effluent. A rain simulator allowed even irrigation of the
soil surface. The composition and amount of rainwater supplied corresponded to that determined at the site of sampling. About $300(\mu \mathrm{Ci}){ }^{85} \mathrm{Sr}$ (carrier-free) and about $50(\mu \mathrm{Ci}){ }^{137} \mathrm{Cs}(3(\mu \mathrm{~g}$ $\mathrm{Cs}) / 100(\mu \mathrm{Ci})$ ) were added with one portion of rainwater to the soil surface. The distribution of the radionuclides in the soil was measured from the outside after various time intervals, using a gamma-scanner technique. Because of the gamma-scanner technique ${ }^{85} \mathrm{Sr}$ was used to simulate the beta-emitter ${ }^{90} \mathrm{Sr}$.
The data in Table 6.2-1 and 6.2-2 are based on Fig. 3 of [14]. They were gained with high precision by means of the digitizing program WinDig 2.5 (©). Lovy, Geneva).These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.2-1 and 6.2-2 with Eq. (6-1) leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.2-3 and 6.2-4.
Table 6.2-5 contains the Weibull-parameters a, n, which are based on 2-dimensional nests of intervals, and Table 6.2-6 contains the figures concerning the sector-method. They indicate a very small scattering of the $\mathrm{x}_{\mathrm{s}}$-values around the $\mathrm{x}_{\mathrm{s}}$-fit. Fig. 6.2-1 demonstrates the almost perfect matching of the centres of gravity and of the penetration depths in the case of time series 1. Table 6.2-7 contains the relevant fitting results for time series 1 and 2. Fig. 6.2-2 exhibits the relative concentrations and Fig. 6.2-3 the inventories below $x$ (\%), in both cases for different points of time for time series 1, and Fig. 6.2-4 demonstrates for time series 1 the relative concentrations after 10 (a), resulting from different models. It's again obvious that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils. Table $6.2-8$ proves that D and v have no real physical meaning; they are just fitting parameters.

Time series 2 is characterized by Fig. 6.2-5 to 6.2-8. The comments concerning time series 1 are also applicable to time series 2 .
Fig. 6.2-9 demonstrates by means of the retention in the upper $10(\mathrm{~cm})$ the different behaviour of ${ }^{737} \mathrm{Cs}$ and ${ }^{85} \mathrm{Sr}$.

### 6.3 Case study 3

Case study 3 is based on [15]. This paper deals with the transport of Chernobyl ${ }^{137} \mathrm{Cs}$ in 2 grassland sites. The near-field site of the Chernobyl nuclear power plant (ChNPP) is located at a distance of $3(\mathrm{~km})$ from the former village Chistogalovka, about $6(\mathrm{~km})$ west-south-west of ChNPP. The mean annual precipitation is $590(\mathrm{~mm})$, and the mean annual temperature is $6.5\left({ }^{\circ} \mathrm{C}\right)$. The sampling location in Germany is situated $40(\mathrm{~km})$ north-west of Munich, $545(\mathrm{~m})$ above sea level. The mean annual precipitation is $800(\mathrm{~mm})$, and the mean annual temperature is $7.3\left({ }^{\circ} \mathrm{C}\right)$. All samples were taken on a flat area to exclude precipitation run-off. The soil, undisturbed by agricultural processes for at least 40 (a), is classified as Parabrown earth soil, paraverglyt. In the US-system this corresponds to a slightly wet Alfisol (Aqualf). The soil at the near-field site of the ChNPP is a soddy-podzolic loamy sand on sandy fluvioglacial deposits. The soil was ploughed formerly (more than 10 (a) ago), and the genetic profile of this soil has been formed under the influence of cultivation, resulting in the formation of an organo-mineral horizon up to 20 ( cm ) thick. The soil samples were mostly taken annually since 1987. At the ChNPP-site soil cores (4 replicates) were extracted to a depth of $10(\mathrm{~cm})$ with a stainless steel sampler (diameter $100(\mathrm{~mm})$ and subsequently cut into slices of $1(\mathrm{~cm})$ thickness. It is not mentioned, whether mixed samples were used for the gamma spectrometry. At the German site the soil samples were taken with a frame ( $50(\mathrm{~cm}) \times 50(\mathrm{~cm})$ ). The sampling depth was $40(\mathrm{~cm})$. Sample preparation was performed in the usual way. ${ }^{134} \mathrm{Cs}$ and ${ }^{137} \mathrm{Cs}$ were determined by direct gamma spectrometry, using a high
purity germanium detector and a multichannel analyser. The Chernobyl ${ }^{137} \mathrm{Cs}$ was, for the German site, determined by means of the ${ }^{134} \mathrm{Cs} /{ }^{137} \mathrm{Cs}$-ratio. At the ChNPP-site the contribution of ${ }^{137} \mathrm{Cs}$ from the global fallout is negligible to Chernobyl-derived ${ }^{137} \mathrm{Cs}$, and therefore no corrections are required. It should be stressed that the speciation of the fallout influences its transport in the soil. At the near-field site the fallout is dominated by fuel particles, and at greater distances aerosols prevail.

The data in Table 6.3-1 and 6.3-2 are based on Fig. 1 of [15]. They were gained with high precision by means of the digitizing program WinDig 2.5 (© D. Lovy, Geneva).These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.3-1 and 6.3-2 with Eq. (6-1) leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.3-3 and 6.3-4.

Table 6.3-5 contains the Weibull-parameters a, n, which are based on 2-dimensional nests of intervals, and Table 6.3-6 contains the figures concerning the sector-method. Fig. 6.3-1 demonstrates the matching of the centres of gravity and of the penetration depths in the case of time series 1 (German site). Fig. 6.3-2 and 6.3-3 show irregularities (relative concentrations and inventories below x (\%) for different points of time), but they are relatively unimportant compared to the results achieved by theoretical models (Fig. 6.3-4, relative concentrations after 20 (a)). It's again obvious that theoretical models are unable toffrecast the transport of ${ }^{137} \mathrm{Cs}$ in soils. Table 6.3-7 contains the relevant fitting results for time series 1 (German site) and time series 2 (ChNPP-site). Table 6.3-8 proves that D and have no real physical meaning; they are just fitting parameters.

Time series 2 is characterized by Fig. 6.3-5 to 6.3-8. There are no irregularities. The matching of the centres of gravity and of the penetration depths (Fig. 6.3-5) is almost perfect, and the sequence of the relative concentration maxima for different points of time in Fig. 6.3-6 is excellent. Fig. 6.3-8 proves again that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils.

A comparison of the results achieved for time series 1 and 2 reveals the different behaviour of different speciations in soils.

### 6.4 Case study 4

Case study 4 is based on [9]. This paper deals with the transport of Chernobyl ${ }^{137} \mathrm{Cs} .3$ sampling areas were selected in the mountainous area of the Friuli-Venezia Giulia region, where the ${ }^{137} \mathrm{Cs}$ deposition following the Chernobyl accident ranged from 20 to $40\left(\mathrm{kBq} \mathrm{m}^{-2}\right)$. Areas 1 and 2 are natural grassland, and on area 3 medicinal herbs are grown. Table 6.4-1 (Table 1 of [9]) characterizes the soils of the 3 sampling areas. Sampling of soils was carried out with seasonal frequency from July 1987 to July 1992. The samples were taken at distances of at least 1 (m) to avoid interferences. A soil monolith with a surface of $30(\mathrm{~cm}) \times 30(\mathrm{~cm})$ was isolated by digging a trench. Samples were taken to a depth of $20(\mathrm{~cm})$, and the monolith was subsequently cut into layers with a thickness of $5(\mathrm{~cm})$. The error associated with this sampling method is in homogeneous soils, according to the authors of [9], about 20 (\%), but it is unclear what this really means. All soil samples were air-dried and sieved through a $2(\mathrm{~mm})$ mesh. The samples were analysed by gamma spectrometry, using HPGe detectors. The total measured ${ }^{137} \mathrm{Cs}$ was separated into its weapons fallout and Chernobyl contribution, using the ${ }^{137} \mathrm{Cs} /{ }^{134} \mathrm{Cs}$ ratio of 2, measured in rainfall samples of May 1986.

The data in Table 6.4-2 to 6.4-4 are based on Fig. 1 of [9]. They were gained with high precision by means of the digitizing program WinDig 2.5 (© D. Lovy, Geneva).These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.4-2 to 6.4-4 with Eq.
(6-1) leads to the Weibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.4-5 to 6.4-7.
Table 6.4-8 contains the Weibull-parameters a, n, which are based on 2-dimensional nests of intervals, and Table 6.4-9 contains the figures concerning the sector-method. Fig. 6.4-1 demonstrates the very good matching of the centres of gravity and of the penetration depths for time series 1 (area 1). Table 6.4-10 and 6.4-11 contain the relevant fitting results for time series 1 to 3. Fig. 6.4-2 exhibits the relative concentrations and Fig. 6.4-3 the inventories below $x$ (\%), in both cases for different points of time for time series 1, and Fig. 6.4-4 demonstrates for time series 1 the relative concentrations after 40 (a), resulting from different models. Fig. 6.4-4 indicates as well that the exponential model $C(x)$, used in [9], approximates $C 7(x)$ much better than all the theoretical models tested. The Weibull-parameter $n(40)=1.21835(-)$. The more or less acceptable approximation is of course a consequence of the fact that $n$ deviates not too much from 1. Table 6.4-13, based on Table 2 of [9], contains the parameter values of the exponential model for time series 1 to 3 (area 1 to 3). It's again obvious that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils. Table $6.4-12$ proves that D and v have no real physical meaning, they are just fitting parameters.

Time series 2 (area 2) is characterized by Fig. 6.4-5 to 6.4-8. Fig. 6.4-5 demonstrates the almost perfect matching of the centres of gravity and of the penetration depths for time series 2 . Fig. 6.4-6 exhibits the relative concentrations and Fig. 6.4-7 the inventories below $x(\%)$, in both cases for different points of time for time series 2, and Fig. 6.4-8 demonstrates for time series 2 the relative concentrations after 20 (a), resulting from different models. The exponential model $\mathrm{C}(\mathrm{x})$, used in [9], approximates $\mathrm{C} 7(\mathrm{x})$ this time very good, since $\mathrm{n}(20)=1.066(-)$. Further comments concerning time series 1 are also applicable to time series 2 .

Time series 3 (area 3) is characterized by Fig. 6.4-9 to 6.4-12. Fig. 6.4-9 demonstrates a good matching of the centres of gravity and of the penetration depths for time series 3. Fig. 6.4-10 exhibits the relative concentrations and Fig. 6.4-11, this time a little disturbed, the inventories below $\mathrm{x}(\%)$, in both cases for different points of time for time series 3, and Fig. 6.4-12 demonstrates for time series 3 the relative concentrations after 30 (a), resulting from different models. The exponential model $C(x)$, used in [9], approximates $C 7(x)$ this time very poor, since $n(30)=1.46(-)$. Further comments concerning time series 1 and 2 are also applicable to time series 3 .

### 6.5 Case study 5

Case study 5 is based on [8]. This paper deals with the transport of ${ }^{137} \mathrm{Cs}$, originating from bomb fallout (global fallout) and Chernobyl fallout. 2 sampling areas were selected in the mountainous area of the Friuli-Venezia Giulia region, where the ${ }^{137} \mathrm{Cs}$ deposition following the Chernobyl accident ranged from 20 to $40\left(\mathrm{kBq} \mathrm{m}^{-2}\right)$. Area 1 is a natural grassland in a region, where soils originate from ancient alluvium. Area 2 is situated in a beech wood on deep soils, originating from calcareous rocks. Table 6.5-1 (Table 1 and 2 of [8]) characterizes the soils of the 2 sampling areas. Sampling of soils was carried out with seasonal frequency from July 1987 to October 1989. The samples were taken at distances of at least $1(\mathrm{~m})$ to avoid interferences. A soil monolith with a surface of $30(\mathrm{~cm}) \times 30(\mathrm{~cm})$ was isolated by digging a trench. Samples were taken to a depth of 20 to $30(\mathrm{~cm})$, and the monolith was subsequently cut into layers with a thickness of 1 to 5 (cm). In the wood, each horizon (i. e., leaves in various stages of decomposition and humus) was sampled separately. In the natural grassland, soil layers with a thickness of $5(\mathrm{~cm})$ were sampled. The error associated with this sampling method is in homogeneous soils, according to the authors of [8], about 20 (\%), but it is unclear what this really means. All soil samples were air-dried and
sieved through a $2(\mathrm{~mm})$ mesh, and the litter samples were oven-dried at $100\left({ }^{\circ} \mathrm{C}\right)$ and then ground. The samples were analysed by gamma spectrometry, using HPGe detectors. The total measured ${ }^{137} \mathrm{Cs}$ was separated into its weapons fallout and Chernobyl contribution, using the ${ }^{137} \mathrm{Cs} /{ }^{134} \mathrm{Cs}$ ratio of 2, measured in rainfall samples of May 1986. Table 3 and 4 of [8] contain the activities in $\left(\mathrm{Bq} \mathrm{kg}^{-1}\right)$. Multiplication of these activities in $(\mathrm{Bq} \mathrm{kg}$ ) with the thicknesses of the samples and the corresponding densities yields the inventories of the layers in $\left(\mathrm{Bq} \mathrm{cm}^{-2}\right)$. The mean soil density of area 1 is $1.4 \mathrm{E}-3\left(\mathrm{~kg} \mathrm{~cm}^{-3}\right)$. The densities of area 2 range from $1 \mathrm{E}-3\left(\mathrm{~kg} \mathrm{~cm}^{-3}\right)$ (organic horizons) to $1.5 \mathrm{E}-3\left(\mathrm{~kg} \mathrm{~cm}^{-3}\right)$ (mineral soils). The depth profiles were fitted with Eq. (2-9), and $\mathrm{M}_{\infty}$ was treated as an additional fitting parameter, since the sampling depths were not sufficient.

A simultaneous use of the Weibull-parameters a, n, based on Eq. (2-9), concerning the bomb fallout (global fallout) and Chernobyl fallout, contained in Table 6.5-2 and 6.5-3, eases a longterm prognosis of the transport of ${ }^{137} \mathrm{Cs}$ in the soils of the 2 areas. This approach is justified, since the Chernobyl fallout consists, far away from the Chernobyl nuclear power plant (ChNPP), mainly of aerosols, i. e., it has the same speciation as the bomb fallout. Model calculations revealed that it is justified to treat the bomb fallout as a single deposition 30 (a) before the first sampling after the Chernobyl accident.

Table 6.5-4 contains the Weibull-parameters a, n, which are based on 2-dimensional nests of intervals, and Table 6.5-5 contains the figures concerning the sector-method. Fig. 6.5-1 demonstrates the matching of the centres of gravity and of the penetration depths for time series 1 (area 1, ). Table 6.5-6 contains the relevant fitting results for time series 1 and 2. Fig. 6.5-2 exhibits the relative concentrations and Fig. 6.5-3 the inventories below $x$ (\%), in both cases for different points of time for time series 1, and Fig. 6.5-4 demonstrates for time series 1 the relative concentrations after 20 (a), resulting from different models. It indicates as well that the exponential model $C(x)$, used in [8], approximates $C 20(x)$ rather poor. The Weibull-parameter $n(20)=1.4391(-)$. Table $6.5-8$, based on Table 5 of [8], contains the parameter values of the exponential model for time series 1 and 2 (area 1and 2). It's again obvious that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils. Table $6.5-7$ proves that D and v have no real physical meaning, they are just fitting parameters.

Time series 2 (area 2) is characterized by Fig. 6.5-5 to 6.5-8. Fig. 6.5-5 demonstrates the good matching of the centres of gravity and of the penetration depths for time series 2. Fig. 6.5-6 exhibits the relative concentrations and Fig. 6.5-7 the inventories below $x$ (\%), in both cases for different points of time for time series 2, and Fig. 6.5-8 demonstrates for time series 2 the relative concentrations after 20 (a), resulting from different models. The exponential model $\mathrm{C}(\mathrm{x})$, used in [8], approximates C20(x) rather poor. The Weibull-parameter $n(20)=1.35075(-)$. Further comments concerning time series 1 are also applicable to time series 2 .

### 6.6 Case study 6

Case study 6 is based on [7]. This paper deals with the transport of ${ }^{134} \mathrm{Cs}$ and ${ }^{106} \mathrm{Ru}$, originating from Chernobyl fallout. 2 localities were selected, Ivrea and Castagneto Po, situated in the Piemonte region in northern Italy. Sampling was performed in unused parts of residential gardens over a period of about 3 (a). Table 6.6-1 (Table 1 of [7]) characterizes the soils of the 2 sampling areas. Nothing is said in [7] about the vegetation. The soils were only sampled to a depth of 4 $(\mathrm{cm})$ and cut into layers of $1(\mathrm{~cm})$. Samples were prepared in the usual way, and the spectrometry was performed by means of a HPGe detector and an 8000-channel pulse-height analyser.

The data in Table 6.6-2 to 6.6-5 are based on Table 3 of [7]. These data are the basis of all
further calculations. Fitting of the depth profiles in Table 6.6-2 to 6.6-5 with Eq. (2-9) leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.6-6 to 6.6-9.

Table 6.6-10 contains the Weibull-parameters a, $n$, which are based on 2-dimensional nests of intervals, and Table 6.6-11 contains the figures concerning the sector-method. The fitting results for time series 1 to 4 are presented in Table 6.6-12 and 6.6-13. Table 6.6-14 proves that $D$ and v have no real physical meaning, they are just fitting parameters.

Time series 1 to 4 are characterized by Fig. 6.6-1 to 6.6-16. Fig. 6.6-1, 6.6-5, 6.6-9, and 6.6-13 demonstrate the perfect resp. almost perfect matching of the centres of gravity and of the penetration depths. Fig. 6.6-4, 6.6-8, 6.6-12, and 6.6-16 demonstrate clearly that theoretical models are unable to forecast the transport of radionuclides in soils.

Fig. 6.6-17 shows the somewhat different behaviour of ${ }^{134} \mathrm{Cs}$ and ${ }^{106} \mathrm{Ru}$ in the 2 soils concerned.

### 6.7 Case study 7

Case study 7 is based on [16]. This paper deals with the transport of ${ }^{137} \mathrm{Cs}$ in different soils. Table 6.7-1 (Table 1 of [16]) characterizes the 4 soils concerned. The soils were placed in concrete cylinders, $0.9(\mathrm{~m})$ dia. and $0.9(\mathrm{~m})$ deep. These concrete cylinders were sited along a bank and buried in soil to within $5(\mathrm{~cm})$ of their rims to minimize temperature changes. A $5(\mathrm{~cm})$ layer of gravel was placed at the bottom of each cylinder and coyered with a $2.5(\mathrm{~cm})$ layer of sand. The cylinders were filled with soil which had been screened through a $2.5(\mathrm{~cm})$ sieve. During the following 9 month extra soil was added as necessary to maintain the soil surface $10(\mathrm{~cm})$ below the rims of the cylinders. In June 1958, the surface was uniformly contaminated with a solution of carrier-free ${ }^{137} \mathrm{Cs}$ at a rate equivalent to $3.7\left(\mathrm{mCi} \mathrm{m}{ }^{-2}\right)$. The surfaces were left bare and maintained free of weeds. Soil cores, $2(\mathrm{~cm}$ ) dia., were withdrawn annually, mostly duplicate cores, and divided into $2.5(\mathrm{~cm})$ fractions. These were counted directly with a well-type gammascintillation counter.

The data in Table 6.7-2 to 6.7-5 are based on Table 2 of [16]. These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.7-2 to 6.7-5 with Eq. (2-9) leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.7-6 to 6.7-9.

Table 6.7-10 contains the Weibull-parameters a, $n$, which are based on 2-dimensional nests of intervals, and Table 6.7-11 contains the figures concerning the sector-method. The fitting results for time series 1 to 4 are presented in Table 6.7-12 and 6.7-13. Table 6.7-14 proves that D and v have no real physical meaning, they are just fitting parameters.

Time series 1 to 4 are characterized by Fig. 6.7-1 to 6.7-16 and by Fig. 6.7-9a. Fig. 6.7-1, 6.7-5, 6.7-9, and 6.7-13 demonstrate the matching of the centres of gravity and of the penetration depths. The quality of the approximations ranges from still acceptable to almost perfect. Fig. 6.7-9a demonstrates that fitting of $n(t)$ in 2 pieces leads to an excellent approximation. Fig. 6.7-4, 6.7-8, 6.7-12, and 6.7-16 demonstrate clearly that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{C}$ in soils.

### 6.8 Case study 8

Case study 8 is based on [17]. This paper deals with the transport of ${ }^{90} \mathrm{Sr}$ in the soils characterized in Table 6.7-1 (Table 1 of [16]). Besides a solution of carrier-free ${ }^{137} \mathrm{Cs}$ at a rate equivalent to 3.7 $\left(\mathrm{mCim}{ }^{-2}\right)$, carrier-free ${ }^{90} \mathrm{Sr}$ was homogeneously applied to the soil surface at a rate equivalent to $0.4\left(\mathrm{mCi} \mathrm{m}^{-2}\right)$.

The data in Table 6.8-1 to 6.8-4 are based on Table 2 of [17]. These data are the basis of all
further calculations. Fitting of the depth profiles in Table 6.8-1 to 6.8-4 with Eq. (2-9) leads to theWeibull-parameters a, n in Table 6.8-5 to 6.8-8.

Table 6.8-9 contains the Weibull-parameters a, $n$, which are based on 2-dimensional nests of intervals, and Table 6.8-10 contains the figures concerning the sector-method. The fitting results for time series 1 to 4 are presented in Table 6.8-11 and 6.8-12. Table 6.8-13 proves that D and v have no real physical meaning, they are just fitting parameters.

Time series 1 to 4 are characterized by Fig. 6.8-1 to 6.8-16. Fig. 6.8-1, 6.8-5, 6.8-9, and 6.8-13 demonstrate the matching of the centres of gravity and of the penetration depths. The quality of the approximations ranges from acceptable to almost perfect. Fig. 6.8-7 shows a small disturbance. Fig. 6.8-4, 6.8-8, 6.8-12, and 6.8-16 demonstrate clearly that theoretical models are unable to forecast the transport of ${ }^{90} \mathrm{Sr}$ in soils.
Fig. 6.8-17 to 6.8-20 show the different behaviour of ${ }^{137} \mathrm{Cs}$ and ${ }^{99} \mathrm{Sr}$ in the 4 soils concerned.

### 6.9 Case study 9

Case study 9 is based on [18]. This paper deals with the transport of Chernobyl ${ }^{137} \mathrm{Cs}$ in several soils of the $30-\mathrm{km}$ restriction zone of the Chernobyl nuclear power plant (ChNPP). Table 6.9-1 (extract from Table 1 of [18]) contains information about the 4 experimental sites concerned and the fallout, and Table 6.9-2 (extract from Table 2 of [18]) characterizes 3 of the 4 soils concerned. Soil cores with 5 or $10(\mathrm{~cm})$ dia. were sampled to a maximum depth of $40(\mathrm{~cm})$ and sectioned horizontally at different intervals. The soil samples were air-dried, ground and passed through a $2-\mathrm{mm}$ sieve before radiometric analysis. ${ }^{137} \mathrm{Cs}$ in the soil samples was determined directly by gamma spectrometry, using a HPGe detector, coupled to a multichannel analyser.

The data in Table 6.9-3 to 6.9-6 are based on Table 3 of [18]. These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.9-3 to 6.9-6 with Eq. (2-9) leads to theWeibull-parameters a , n in Table 6.9-7 to 6.9-10.

Table 6.9-11 contains the Weibull-parameters a, n , which are based on 2-dimensional nests of intervals, and Table 6.9-12 contains the figures concerning the sector-method. The fitting results for time series 1 to 4 are presented in Table 6.9-13 and 6.9-14. Table 6.9-15 proves that D and $v$ have no real physical meaning, they are just fitting parameters.

Time series 1 to 4 are characterized by Fig. 6.9-1 to 6.9-16. Fig. 6.9-1, 6.9-5, 6.9-9, and 6.9-13 demonstrate the matching of the centres of gravity and of the penetration depths. The quality of the approximations ranges from excellent to perfect. The excellent approximations in the case of Fig. 6.9-5 are achieved by fitting $n(t)$ in 2 pieces. The fitting equation for the second part of $n(t)$ is

$$
f_{8}(t)=b \cdot(t+c)^{\frac{1}{m}}+d^{(6-3)}
$$

Fig. 6.9-2 $(\mathrm{Cl}(\mathrm{x}))$ and 6.9-7 $(\mathrm{p} 1(\mathrm{x}))$ show disturbances. Fig. 6.9-4, 6.9-8, 6.9-12, and 6.9-16 $\overline{\text { demonstrate clearly that theoretical models are unable to forecast the transport of Chernobyl }{ }^{131} \mathrm{Cs}}$ in soils.

### 6.10 Case study 10

Case study 10 is based on [19]. This paper deals with the transport of Chernobyl ${ }^{137} \mathrm{Cs}$ in an undisturbed soil of the university farm of Thessaloniki (northern Greece). Table 6.10-1 (Table

1 of [19]) characterizes the soil concerned. The total deposition of ${ }^{137} \mathrm{Cs}$ at the site was 20 $\left(\mathrm{kBq} \mathrm{m}^{-2}\right)$. The contribution of weapons fallout was found to be negligible. Soil samples were periodically collected from 1987 to 1994 from a $10(\mathrm{~m}) \times 10(\mathrm{~m})$ area. Slices of soil with a cross section of $50\left(\mathrm{~cm}^{2}\right)$ and a height of $5(\mathrm{~cm})$ were collected to a depth of $30(\mathrm{~cm})$. The soil samples were air-dried, ground, and passed through a $2-\mathrm{mm}$ sieve. ${ }^{137} \mathrm{Cs}$ in the soil samples was determined directly by gamma spectrometry, using a HPGe detector, coupled to a multichannel analyser.

The data in Table 6.10-2 are based on Fig. 1 of [19]. They were gained with high precision by means of the digitizing program WinDig 2.5 (© D. Lovy, Geneva). These data are the basis of all further calculations. Fitting of the depth profiles in Table 6.10-2 with Eq. (2-9) leads to theWeibull-parameters $\mathrm{a}, \mathrm{n}$ in Table 6.10-3.

Table 6.10-4 contains the Weibull-parameters a, $n$, which are based on 2-dimensional nests of intervals, and Table 6.10-5 contains the figures concerning the sector-method. They indicate a comparatively small scattering of the $\mathrm{x}_{\mathrm{s}}$-values around the $\mathrm{x}_{\mathrm{s}}$-fit. The fitting results for time series 1 are presented in Table $6 \cdot 10-6$. Table $6 \cdot 10-7$ proves that D and v have no real physical meaning, they are just fitting parameters.

Time series 1 is characterized by Fig. 6.10-1 to 6.10-4. Fig. 6.10-1 demonstrates the matching of the centres of gravity and of the penetration depths. The quality of the approximations was improved by fitting $n(t)$ in 2 pieces. Fig. 6.10-3 shows minor disturbances. Fig. 6.10-4 demonstrates once again that theoretical models are unable to forecast the transport of ${ }^{137} \mathrm{Cs}$ in soils.

## 7. Conclusions

All theoretical models treated failed to forecast the transport of radionuclides in soils. The solution of the ADE, Eq. (2-2), even violates for certain data sets of $D$, $v$, and $t$ the mass conservation law. By means of the integral method excellent fitting results are achieved for the modelling of depth distributions. It can be argued that the fitting results $D$ and $v$ have no real physical meaning, they are just fitting parameters which depend often heavily on the startingvector. It is thus unfortunately not sufficient to achieve excellent fitting results. Because of the complexity of the transport of radionuclides in soils and sediments one can argue that any theoretical model is unable to forecast the transport of radionuclides in soils and sediments. This cognition has probably inspired certain workers in the field to employ an empirical approach, but their choice, to employ the simple exponential function for time series analysis, is no general solution of the problem. An empirical approach, based on time series analysis by means of the time dependant Weibull-distribution, is, on the contrary, able to solve the transport problem in question generally.

A critical study of the relevant literature revealed that workers in the field are often not fully aware of the importance of sampling, but a problem oriented sampling strategy improves the reliability of a prognosis.

C7(x): relative concentration after 50 (a)
$C(x)$ : relative concentration after $50(a)$, based on second fits of $a(t)$ and $n(t)$

Fig. 6.1-6: Inventories below x in (\%) for different points of time (time series 1, Cs-137) legend:
ordinate axis: inventories below x (\%)
$\mathrm{pl}(\mathrm{x})$ : inventory below x in (\%) after 0.332 (a)
$\mathrm{p} 2(\mathrm{x})$ : inventory below x in (\%) after 1.343 (a)
$\mathrm{p} 3(\mathrm{x})$ : inyentory below x in (\%) after 3.836 (a)
$\mathrm{p} 4(\mathrm{x})$ : inventory below x in (\%) after 7.588 (a)
based on 2-dimensional nest of intervals $\mathrm{p} 5(\mathrm{x})$ : inventory below x in (\%) after 15 (a)
$\mathrm{p} 6(\mathrm{x})$ : inventory below x in (\%) after 30 (a)
$\mathrm{p} 7(\mathrm{x})$ : inventory below x in (\%) after 50 (a)
$\mathrm{p}(\mathrm{x})$ : inventory below x in (\%) after $50(\mathrm{a})$, based on second fits of $\mathrm{a}(\mathrm{t})$ and $\mathrm{n}(\mathrm{t})$

Fig. 6.1-7: Relative concentrations after 50 (a), resulting from different models (time series 1, Cs-137)
legend:
ordinate axis: relative concentration ( $\mathrm{cm}^{-1}$ )
C 7 (x) : relative concentration after 50 (a), based on 2-dimensional nest of intervals $\mathrm{Csa}(\mathrm{x})$ : relative concentration after 50 (a), based on Eq. (2-2), a-profile Csl(x) : relative concentration after 50 (a), based on Eq. (2-2), 1-profile Cqsa(x): relative concentration after 50 (a), based on Eq. (2-3), a-profile Cqsl(x) : relative concentration after 50 (a), based on Eq. (2-3), 1-profile $\mathrm{Ctfa}(\mathrm{x})$ : relative concentration after 50 (a), based on Eq. (2-4), a-profile $\mathrm{Ctfl}(\mathrm{x})$ : relative concentration after 50 (a), based on Eq. (2-4), 1-profile

Fig. 6.1-8: Primary photon fluence rates, resulting from different models (time series 1, Cs-137)
legend:
ordinate axis: primary photon fluence rate $\left(\mathrm{cm}^{-2} \mathrm{~s}^{-1}\right)$
$\Phi \mathrm{W}(\mathrm{t})$ : primary photon fluence rate; concentration based on Eq. (2-5)
$\Phi s a(t)$ : primary photon fluence rate; concentration based on Eq. (2-2), a-profile
$\Phi s l(\mathrm{t})$ : primary photon fluence rate; concentration based on Eq. (2-2), 1-profile
$\Phi q s a(t)$ : primary photon fluence rate; concentration based on Eq. (2-3), a-profile
$\Phi q \mathrm{ll}(\mathrm{t})$ : primary photon fluence rate; concentration based on Eq. (2-3), 1-profile
$\Phi t f a(t)$ : primary photon fluence rate; concentration based on Eq. (2-4), a-profile $\Phi \operatorname{tfl}(\mathrm{t})$ : primary photon fluence rate; concentration based on Eq. (2-4), 1-profile

Fig. 6.1-9: Integrated primary photon fluence rates, resulting from different models (time series 1, Cs-137)
legend:
ordinate axis: integrated primary photon fluence rate $\left(\mathrm{cm}^{-2} \mathrm{~s}^{-1} \mathrm{a}\right)$ $\Phi I W(\mathrm{t})$ : integrated primary photon fluence rate; concentration based on Eq. $(2-5)$ $\Phi I s a(t)$ : integrated primary photon fluence rate; concentration based on Eq. (2-2), a-profile $\Phi \operatorname{Isl}(\mathrm{t})$ : integrated primary photon fluence rate; concentration based on Eq. (2-2), 1-profile $\Phi \operatorname{Iqsa}(\mathrm{t})$ : integrated primary photon fluence rate; concentration based on Eq. (2-3), a-profile $\Phi \operatorname{Iqs}(t)$ : integrated primary photon fluence rate; concentration based on Eq. (2-3), 1-profile $\Phi \mathrm{Itfa}(\mathrm{t})$ : integrated primary photon fluence rate; concentration based on Eq. (2-4), a-profile $\Phi \operatorname{Itfl}(\mathrm{t})$ : integrated primary photon fluence rate; concentration based on Eq. (2-4), 1-profile

Remark: The primary photon fluence rates are, for practical reasons, integrated over the time $t$ in (a). If the time $t$ is expressed in (s), the integrated primary photon fluence rates have to be multiplied by the factor 31536000 . The real dimension of the integrated primary photon fluence rate is of course $\left(\mathrm{cm}^{-2}\right)$.
