## **Acknowledgements**

When I decided to accept a PhD position at the Geobotany Department of the University of Trier some years ago, I could not have dreamt what impact this decision would have on both my professional as well as my private life. The combination of bio-monitoring and flux modelling methods presented in this thesis has over the course of the years opened various doors for me and has led me from Trier via Wales to England, where I currently work for the Stockholm Environment Institute. On this long and sometimes winding path I have met numerous people, some of which have become close colleagues and even friends.

There is no doubt that this thesis would have been impossible without the kind and self-sacrificing help of some of these lovely people who in one or another way have contributed to make this thesis a success story. I am deeply indebted to these people for their comments, support and general commitment and would like to individually thank them in the following:

First of all, I owe my deepest thanks to Prof. Dr. Willy Werner who has supervised my work throughout the entire period of this PhD thesis. It was he who initiated my interest in bio-monitoring methods and eco-physiology in general during my university years in Trier and I cannot thank him enough for it. His genuine enthusiasm, continuous support, sharp and constructive comments as well as the practical help during measuring campaigns have always been very welcomed.

Further thanks go to Professor Dr. Joachim Hill, who kindly agreed to co-supervise this thesis, a timely and not insignificant task I certainly do not take for granted. His time spent on this task is very much appreciated.

I would also like to express my deep gratitude to Dr. Lisa Emberson for her endless support, the lively discussions about the pros and cons of various flux models and for the introduction to the exciting world of air pollution impact modelling in developed and developing countries in general.

During my 10-month stay at the ICP Vegetation Coordination Centre in Bangor, Wales, Dr. Gina Mills and Dr. Harry Harmens have been my local hosts, a task they fulfilled with

perfection. I certainly intensified my knowledge on bio-monitoring methods during my stay there and would like to thank both Dr. Gina Mills and Dr. Harry Harmens for their hospitality.

Further colleagues who contributed to this thesis through fruitful discussions, helping hands and general encouragement were Dr. Jürgen Franzaring, Dr. Andreas Golisch, Eva Linke, Sven Wehke, Dr. Simone Klatt, Karen Heidemann, Thomas Frankenberg and Dr. Johan Uddling. Without them the PhD years would have only been have as exciting. Many thanks to all of you!

On a more personal note, I would like to thank all friends who have accompanied me during the years of my PhD thesis – they always had an ear for my concerns and certainly have contributed a lot to me actually finalising the “PhD project”. I would amongst others particularly like to mention here Achim, Anja, Thomas, Annette, Birgit, Simone, Andreas, Walle, Nia and Seema.

Furthermore, I owe my deep gratitude to my parents Horst and Heide and my siblings Johanna and Nik – you have been amazing in constantly supporting me and believing in this project. Your support means a lot to me and I have decided to dedicate this thesis to all of you!

Last but certainly not least, I would like to deeply thank my partner Stefan for his patience over the years and the sacrifices he often had to make while I was writing up this thesis. This is almost as much your piece of work as it is mine. Thank you so much!

Patrick Büker

## 1. Introduction

Over the last two decades, ozone ( $O_3$ ) has become the most discussed air pollutant among scientists, politicians and the general public. Its widespread occurrence in the stratosphere and troposphere, its direct participation in some of the severest environmental problems mankind has to deal with at present, such as the depletion of the so called stratospheric ozone-layer, the decline of forests and reduced harvests of staple crops due to increasing tropospheric  $O_3$  concentrations, the difficulties in predicting future atmospheric  $O_3$  concentrations and the unknown dependence of these predictions on suggested climate change scenarios and vice versa, has put this air pollutant in the focus of many research projects.

Most of the atmospheric  $O_3$  molecules are found in the stratosphere (altitude of approx. 10-15 km up to 45 km), where the breaking down of molecular oxygen ( $O_2$ ) into free oxygen atoms (O) by short-wave radiation and the subsequent reaction of these atoms with oxygen leads to the formation of  $O_3$ . The  $O_3$  concentrations in the stratosphere have declined substantially over the last decades, an effect which is believed to be linked to an increase in persistent atmospheric air pollutants such as chlorofluorocarbons. This effect influences life on earth since the stratospheric  $O_3$  is needed to filter the UV-radiation, which is known to damage human, animal and plant cuticles.

In contrast, the  $O_3$  concentrations in the troposphere, i.e. the lower part of the atmosphere up to a height of approx. 10-15 km, have increased during the last decades due to biogenic and anthropogenic emissions. Ground level  $O_3$  directly affects organisms on earth, because it is taken up by human beings, animals and plants via respiration. The impact of  $O_3$  on plants and in particular on white clover will be the focus of this thesis.

The evidence of impacts of  $O_3$  on plants in general has become increasingly important for high-level political negotiations (e.g. within the UNECE, UNEP, GAP Forum etc.) on strategies for the abatement of transboundary air pollutants, such as  $O_3$ . As a consequence, an effect-based approach using experimentally derived critical levels for  $O_3$  has been developed to reduce  $O_3$  concentrations and their impacts on vegetation across Europe. While impacts of  $O_3$  on plants, such as visible foliar injury or reductions

of biomass, were traditionally related to O<sub>3</sub> exposure metrics, e.g. the AOT40 index (accumulated exposure over a threshold of 40 ppb), there is now general agreement that these ozone-induced impacts are more closely related to the O<sub>3</sub> dose absorbed through the stomata (Ashmore et al., 2004a,b). This led to an increasing interest in the development of appropriate O<sub>3</sub> flux models mainly based on stomatal conductance ( $g_s$ ).

This thesis will present a new approach for modelling  $g_s$  based on artificial neural networks (ANNs), as well as the application of the developed  $g_s$  models to meteorological time-series data for the predictions of O<sub>3</sub> fluxes.

## **1.1 Formation, distribution and trends of tropospheric ozone**

### ***1.1.1 Formation of tropospheric ozone***

Until the 1970s the main source of tropospheric O<sub>3</sub> was believed to be the stratosphere, from where the O<sub>3</sub> had directly been transported into the troposphere. Only in highly polluted urban areas, such as Los Angeles, where some of the first adverse effects of air pollution on plants were observed in the 1940s (Middleton et al., 1950), the photochemical production of O<sub>3</sub> was considered as being important. However, Crutzen (1973), Fishman et al. (1979) and others showed first evidence that the photochemical production of O<sub>3</sub> from precursors such as nitrogen oxides (NO<sub>x</sub>) and organic compounds (VOC) forms the major source of O<sub>3</sub> in the troposphere. In fact, Fowler et al. (1998) recently stressed the importance of oxidised nitrogen, which today accounts for approximately 70% of the total global emissions (Kasibhatla et al., 1993) for O<sub>3</sub> formation.

This clearly defines O<sub>3</sub> as a secondary air pollutant directly connected with anthropogenic activity. Apart from biogenic VOC emissions such as terpenes and isoprene (Simpson et al., 1995), which in comparison with anthropogenic emissions are believed to be a minor source of O<sub>3</sub> precursors, the main sources for the above mentioned precursors are transport, domestic heating, industry, and energy production, all of which are related to fossil fuel combustion (Warneck, 1988; Fuchs, 1994).

Given the high reactivity and oxidation potential of O<sub>3</sub> (Schröter et al., 1991), an equilibrium, called the “NO-photostationary state equation” (Stockwell et al., 1997),

between O<sub>3</sub> production and O<sub>3</sub> destruction would exist in the absence of air pollutants. On the one side, the photolysis of NO<sub>2</sub> by radiation (exactly: photon energy  $h\nu$ ) of wavelength smaller than 420 nm forms the basis for the O<sub>3</sub> formation (Finlayson-Pitts & Pitts, 2000):

Subsequently, the single oxygen atom reacts with an oxygen molecule to form an O<sub>3</sub> molecule (M is either a nitrogen or oxygen molecule):

On the other side, O<sub>3</sub> is destroyed by reacting with NO to reproduce NO<sub>2</sub> (Finlayson-Pitts & Pitts, 2000):

Generally, this reaction takes place in the absence of light, i.e. during night-time hours. However, this equilibrium collapses in the presence of VOCs and carbon monoxide, all of which react with radicals produced by the photolysis of O<sub>3</sub>. In a first step, one of the O<sub>3</sub> photolysis reactions produces an excited oxygen atom, O(<sup>1</sup>D) (Stockwell et al., 1997):

A fraction of the excited oxygen atoms reacts with water to produce the hydroxyl radical, HO•:

The hydroxyl radicals react with VOCs (in the following expressed as RH = organic compounds) and carbon monoxide to produce organo-peroxy (RO<sub>2</sub>•) and hydro-peroxy (HO<sub>2</sub>•) radicals (Stockwell et al., 1997):

These peroxy radicals oxidise NO to NO<sub>2</sub> without any consumption of O<sub>3</sub>, which leads to an increase of the tropospheric O<sub>3</sub> concentration (Stockwell et al., 1997):

### 1.1.2 Distribution of tropospheric ozone

On a local scale, the distribution of O<sub>3</sub> is somewhat untypical for an air pollutant because of its usually higher concentrations in sub-urban and rural compared to urban areas. However, the source of rural O<sub>3</sub> concentrations are generally urban agglomerations, from where the O<sub>3</sub> is transported by winds to surrounding areas.

Figure 1.1 Average hourly O<sub>3</sub> concentrations at the urban, suburban and rural site Trier-City, Trier-University and Deuselbach, respectively. Shown are the means of half-hourly measurements carried out in July and August 1997 (62 days).

A typical diurnal course of tropospheric O<sub>3</sub> concentrations for an urban, suburban and rural site in the Trier region is presented in Figure 1.1. During the early morning hours, O<sub>3</sub> concentrations are at a minimum due to surface deposition and nitric oxide emissions. With increasing commuter traffic later in the morning, NO-emissions rise.

The oxidation of NO to NO<sub>2</sub> and the high solar radiation form the basis for an increase in O<sub>3</sub> concentrations with a relative maximum in the early afternoon. In the early evening hours, O<sub>3</sub> concentrations decrease again due to the decreasing solar radiation and increased NO-emissions from commuter traffic.

Although this pattern is valid for all sites, the curves for the urban, suburban and rural site (Trier-City, Trier-University and Deuselbach, respectively) shown in Figure 1.1 differ in their O<sub>3</sub> concentration level and in their daily amplitude. A typical diurnal time-course of urban and suburban O<sub>3</sub> concentrations is characterised by a high concentration amplitude (Alexander & Drüeke, 1992; Fuchs, 1994), which is in particular the case for the site Trier-University in Figure 1.1.

In contrast, in rural areas such as Deuselbach the amplitude of the diurnal course of the O<sub>3</sub> concentration is less pronounced due to less traffic and therefore less NO emissions. O<sub>3</sub> and its precursors are typically transported from urban to rural areas. Especially during stable high-pressure weather periods in the summertime, O<sub>3</sub> concentrations in rural areas can therefore substantially exceed urban O<sub>3</sub> concentrations (Figure 1.1) because of a diminished O<sub>3</sub> destruction during night-time due to the lack of traffic-related NO-emissions, which deplete O<sub>3</sub> in the absence of sunlight (cf. 1.1.1, reaction 3). Accordingly, O<sub>3</sub> concentrations accumulate over several days in rural areas during long-term high-pressure weather periods, often leading to the exceedance of O<sub>3</sub> concentration thresholds in these areas (Fellenberg, 1990; Alexander & Drüeke, 1992).

Furthermore, there is evidence that O<sub>3</sub> concentrations increase with increasing altitude (PORG, 1993; UBA, 1994) due to higher NO<sub>2</sub> concentrations at the expense of NO concentrations in uplands. Because of the lack of NO emissions, the diurnal amplitude of the O<sub>3</sub> concentration is very low in high altitudes (e.g. alpine areas) (PORG, 1993).

On a European scale, the annual distribution of O<sub>3</sub> concentrations usually shows a maximum during the summer months, which was also reported from the site Deuselbach (Figure 1.2). Furthermore, the annual variation of O<sub>3</sub> concentrations increases from the Northwest to the Southeast of Europe (Toupance & Aranda, 1993). This effect is mainly related to the spatial distribution of O<sub>3</sub> precursors and the prevailing meteorological conditions, which especially favours the O<sub>3</sub> formation in

Southeast Europe (Davies et al., 1992; Beck & Grennfelt, 1994). Thus, peak O<sub>3</sub> concentrations and the frequency of summertime O<sub>3</sub> episodes are higher in Central and Southern than in Northern Europe.

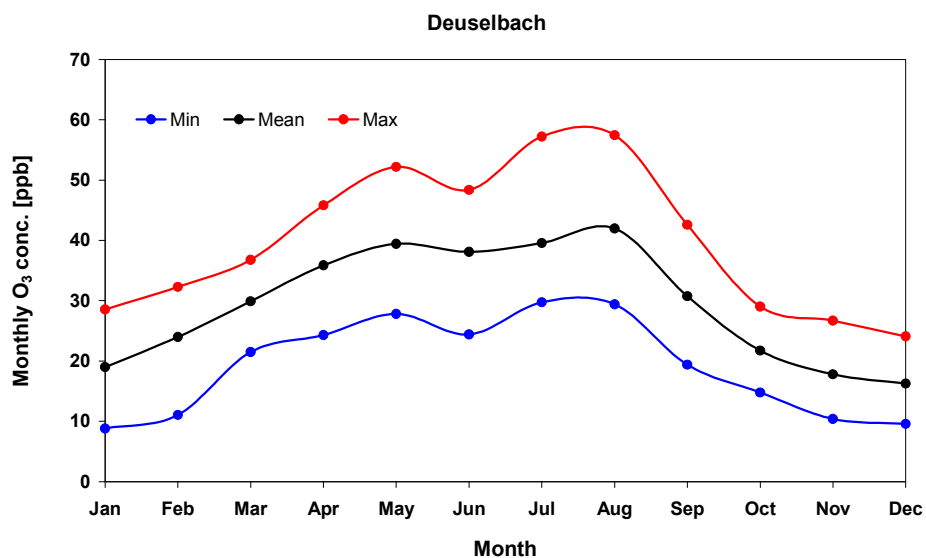

Figure 1.2 Annual time-course of O<sub>3</sub> concentrations measured at the site Deuselbach (Hunsrück, Rhineland-Palatinate) between 1980 and 2003. Shown are the monthly minimum, mean and maximum O<sub>3</sub> concentrations based on half-hourly measurements (UBA, pers. communication).

On a global scale, there is more O<sub>3</sub> in the troposphere of the northern hemisphere than in the troposphere of the southern hemisphere on an annual basis (Oltmans & Levy, 1994). Accordingly, Müller & Brasseur (1995) showed that approximately 80 % of the NO<sub>x</sub> emitted on a global basis is due to anthropogenic activity in the northern hemisphere.

However, for both hemispheres O<sub>3</sub> annual distributions exhibit maxima between April and July (Logan, 1985; Oltmans and Levy, 1994). For the northern atmosphere, the annual course of the O<sub>3</sub> distribution might be related to the seasonality of the stratosphere-troposphere exchange. Danielsen (1968) and Reiter (1975) have shown that the stratospheric O<sub>3</sub> intrusion rate during spring is much higher than during the autumn. However, springtime photochemical O<sub>3</sub> production in remote areas and summer photochemical O<sub>3</sub> production in less remote areas (e.g. cities) might indicate the anthropogenic influence on the diurnal northern hemisphere O<sub>3</sub> distribution (Penkett & Brice, 1986).

### 1.1.3 Trends of tropospheric ozone

Over the course of the 20<sup>th</sup> century, the background surface concentrations of O<sub>3</sub> in Europe have increased by a factor of two to three from their pre-industrial levels (Borrell, 1997). Globally, background tropospheric O<sub>3</sub> levels have risen by approximately 36% since pre-industrial times (IPCC, 2001). Volz & Kley (1988), Anfossi et al. (1991) and Marenco et al. (1994) analysed historical datasets of O<sub>3</sub> concentrations measured in the late 19<sup>th</sup>/early 20<sup>th</sup> century in France and northern Italy and found O<sub>3</sub> background concentrations of 5 ppb (autumn and winter) to 15 ppb (spring and autumn). These results match well with model calculations of Crutzen & Zimmermann (1991).

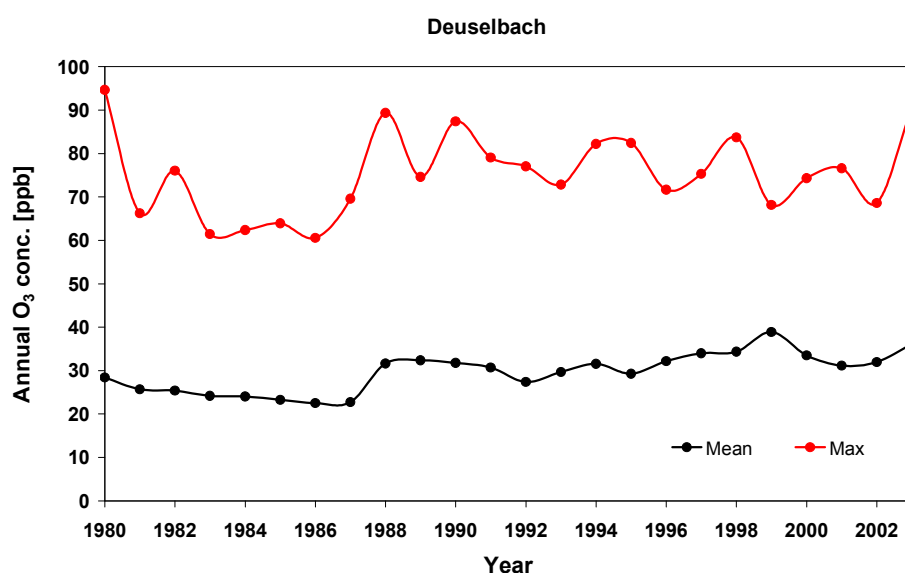

Figure 1.3 Change of annual mean and maximum O<sub>3</sub> concentration (based on half-hourly measurements) at the site Deuselbach (Hunsrück, Rhineland-Palatinate) between 1980 and 2003 (UBA, pers. communication).

Today, tropospheric O<sub>3</sub> background concentrations in central Europe (and elsewhere) are usually in the range of 20 to 40 ppb (the top end during the summer months), with peak O<sub>3</sub> concentrations above 100 ppb (Volz & Kley, 1988; Anfossi et al., 1991; Staehelin et al., 1994; PORG, 1997). The O<sub>3</sub> concentrations trends in Germany are representative for almost all industrialised nations: On the one hand an increase in O<sub>3</sub> background concentrations, on the other hand a stagnation or decline of summer peak concentrations (UBA, 2002), leading to a slight increase in annual mean O<sub>3</sub> concentrations. This trend has also been reported in Deuselbach, one of the experimental sites used in this thesis (Figure 1.3). For the future, these trends are

believed to maintain (Coyle et al., 2003; Vingarzan, 2004), leading to increased daytime mean O<sub>3</sub> concentrations (Ashmore et al, 2002).

Since similar trends have been recognised all over the globe (Emberson et al., 2003), elevated O<sub>3</sub> concentrations are nowadays rated as a hemispherical problem rather than a local or regional one as in the past. This fact results in new challenges for environmental policy, because multi-lateral approaches are needed to protect human beings, animals and plants from adverse O<sub>3</sub> effects. In order to be able to predict future pollutant climates on a local, regional and especially global scale, precise models simulating the atmospheric chemistry, transport and deposition of pollutants such as O<sub>3</sub> are crucial. A comprehensive review of available photochemical oxidant models was published by Fowler et al. (1999b), with special focus on challenges these models will have to face in the future.

Just recently, the scientific community addressed the question of the interaction of air pollutants, in particular O<sub>3</sub>, and expected global climate change. There is general agreement that climate change and regional air pollution should not be investigated separately, since both phenomena are closely related aspects of a changing atmosphere with severe effects on ecosystems (Fuhrer, 2003). In fact, Fuhrer (2003) suggests that beneficial effects of elevated CO<sub>2</sub> concentrations, such as increased O<sub>3</sub> tolerance of plants, might be reduced or even lost with increasing global temperatures.

Furthermore, tropospheric O<sub>3</sub> contributes to global warming by absorbing radiant energy (Graedel & Crutzen, 1993) and is considered to be the third largest driver of the anthropogenic “greenhouse effect” (Prather et al., 2001). In return, global warming is expected to favour the O<sub>3</sub> formation through increased emissions of VOCs from the vegetation (Kellomäki et al., 2001), whereas the direct role of the expected climate change was predicted to be a negative feedback on the increase on O<sub>3</sub> concentrations (Johnson et al., 2001). However, many questions about the interactions between increased CO<sub>2</sub> concentrations, increased temperature and the occurrence of secondary air pollutants (e.g. O<sub>3</sub>) still remain unsolved to date.

## 1.2 Effects of ozone on plants

Toxic effects of tropospheric O<sub>3</sub> on plants have been known for approximately five decades now (Richards et al., 1958). However, not until the 1980's the outstanding role of ground-level O<sub>3</sub> for plant health had been recognized (Krupa & Manning, 1988; Ashmore & Bell, 1991). With increasing background levels of O<sub>3</sub> (Borrell, 1997; Ashmore et al., 2002), its widespread occurrence (Simini et al., 1992) and the decline of other air pollutants (e.g. SO<sub>2</sub>), it has become evident that O<sub>3</sub> currently is and will continue to be the main threat to vegetation in the near future, both in developed and in developing countries (cf. Stockwell et al., 1997; Fowler et al., 1999a; Turcsányi et al., 1999; Emberson et al., 2003; Wang & Mauzerall, 2004).

Generally, plant response mechanisms to air pollutants, such as O<sub>3</sub>, can be defined as either exclusion, tolerance, compensation or repair (Levitt, 1989). The response depends upon the concentration, duration and exposure of the pollutant, environmental conditions, the developmental and metabolic state as well as the detoxification potential of the plant (Guzy & Heath, 1993; Long & Naidu, 2002). The latter is believed to be either genetically predefined or/and dependent on the O<sub>3</sub> history at the site of origin (reflecting a potential adaptation and therefore resistance of the plant to O<sub>3</sub>), which is particularly pronounced for short-living semi-natural species (cf. Lyons et al., 1997). Any response of a plant to a single air pollutant or – more realistically – to a mixture of air pollutants requires a change in its “usual behaviour”, i.e. the plant is forced to spend energy on the reaction to a stressor attack. To a certain extent, this energy is used to compensate for the attack, for example by stomatal closure, production of antioxidants etc. These mechanisms help to maintain all life-dependant plant-physiological processes and to prevent any form of injury. However, the necessity to spent energy on defence mechanisms can reduce the rate of photosynthesis and/or might alter the photosynthate allocation. Nevertheless, usually only after the detoxification threshold - which defines the point above which the plant is not able to compensate for detrimental effects of toxic stressors anymore - is reached, plants will start to show injury symptoms.

The most obvious air pollutant-induced injury symptom is visible foliar injury. Yet over the last decades, further forms of injury has been described, such as reduced plant productivity, shifts in metabolic pathways, decreased ability to compensate for

secondary stresses (e.g. pathogen attack, cf. Matyssek & Innes (1999)) and accelerated senescence.

On a wider scale, these phytotoxic effects of O<sub>3</sub> potentially have the power to pose a critical threat to present and future world food, fibre and timber production (Krupa et al., 2001), as well as to the conservation of natural plant communities, including their species diversity (Ashmore et al., 1995; Davison & Barnes, 1998; Barnes et al., 1999; Krupa et al., 2001).

In order to determine plant injury specifically caused by exposure to O<sub>3</sub>, many laboratory, field-chamber and - more recently - open air experiments have been carried out (e.g. Heagle et al., 1973; Volk et al., 2003; Karnosky et al., 2003; Erbs & Fangmeier, 2005). These experiments have shown that exposure of trees, crops and semi-natural vegetation to O<sub>3</sub> can induce the above mentioned negative impacts on plant health and production, such as visible foliar injury (Sanders & Benton, 1995; Flagler, 1998), premature ageing/senescence (Grandjean & Fuhrer, 1989; Heath & Taylor, 1997), reduction in plant growth and production (Heagle, 1989; Broadmeadow, 1998; Chappelka & Samuelson, 1998; Bortier et al., 2000a), changes in crop quality (Pleijel et al., 1997) and/or a decline in the generative reproductive performance, i.e. amount and dry weight of flowers (Lyons & Barnes, 1998; Gimeno et al., 2004).

### ***1.2.1 Effects of ozone at cellular, biochemical and physiological level***

As a strong oxidant, O<sub>3</sub> affects both external and internal surfaces of plants. While external surfaces, i.e. mainly cuticles, are believed to react with O<sub>3</sub> (e.g. Jetter et al. (1996) and Percy et al. (2002) showed degradation of wax tubules in conifer needles and changes in production and structure of cuticular waxes, respectively) and therefore function as O<sub>3</sub> sinks, there is clear general agreement today that the most harmful effects of O<sub>3</sub> are related to O<sub>3</sub> uptake via the leaf stomata rather than O<sub>3</sub> concentrations in the surrounding air (Musselman & Massman, 1999). Since the cuticle is an effective barrier for O<sub>3</sub> uptake (Kerstiens & Lenzian, 1989), O<sub>3</sub> is entering the plant mainly via the stomata, as had been proved for the first time by Rich et al. (1970).

Interestingly, Laisk et al. (1989) measured internal O<sub>3</sub> concentrations close to zero, which is a clear evidence for the quick reaction of O<sub>3</sub> with molecules in the cell wall and plasma membrane due to ozone's extreme reactivity potential (Heath & Taylor, 1997). In other words, the free path of O<sub>3</sub> in the plant is very short, thus only its oxidative products can diffuse into the cell and react with metabolites and biochemicals in the thylakoid membrane and chloroplast (Heath & Taylor, 1997; Long & Naidu, 2002). The reaction of O<sub>3</sub> with the plasma membrane (the initial site of O<sub>3</sub> injury) or – more precisely – with water-soluble organic molecules in the apoplast leads to the formation of various reactive oxygen species (ROS) which induce radical chain reactions (Grimes et al., 1983; Mehlhorn et al., 1990; Kangasjärvi et al., 1994).

The main ROS which are believed to initiate metabolic changes and subsequently productivity losses are hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), the hydroxyl radical (HO<sup>•</sup>) and superoxide (O<sub>2</sub><sup>•-</sup>) (Tingey & Taylor, 1981). Furthermore, there is clear evidence that the production of the plant hormone ethylene (C<sub>2</sub>H<sub>4</sub>) is highly correlated with O<sub>3</sub> effects, more precisely visible injury (Mehlhorn et al., 1991; Long & Naidu, 2002), or – in other words – ethylene release is stimulated by O<sub>3</sub> exposure (Tingey et al., 1976). Ethylene is known to be responsible for an increased expression of senescence-associated genes and a decreased expression of genes coding for photosynthetic proteins (Miller et al., 1999). There are two main theories about the mechanism of the interaction between O<sub>3</sub>, ethylene and damage: a) An increased ethylene production in response to O<sub>3</sub> exposure induces damage via a signal transduction pathway with ethylene being the signal molecule (Sandermann et al., 1998), and b) ozonolysis of the ethylene molecule may produce ROS (Heath & Taylor, 1997). Thus, the question whether ethylene induces damage directly or via production of ROS is still unanswered. However, there is general agreement that O<sub>3</sub> stress, mechanical wounding and pathogen attack all induce ethylene production in the same way (Heath & Taylor, 1997).

To a certain extent plants are able to detoxify ROS, because the aqueous matrix of the cell wall is known to contain many compounds which can act as antioxidants (Larson, 1988; Moldau, 1998; Turcsányi et al., 2000), including ascorbate (Castillo & Greppin, 1988; Takahama & Oniki, 1992; Luwe et al., 1993; Deutsch, 1998), polyamines and phenolics (Langebartels et al., 1991; Eckey-Kaltenbach et al., 1994), and glutathione (Polle et al., 1990; Jamaï et al., 1996), as well as enzymes protecting against ROS, such

as (Cu/Zn) superoxide dismutase (Steller & Wingsle, 1994; Ogawa et al., 1996; Lyons et al., 1999) and peroxidases (Castillo et al., 1984, 1987; Castillo & Greppin, 1986; Takahama & Oniki, 1992; Polle et al., 1994; Ranieri et al., 1996; Torsethaugen et al., 1997). The concentration of these antioxidants and enzymes varies with plant species and the leaf's developmental stage and can be enhanced by an O<sub>3</sub> attack, as has been shown for peroxidases (Castillo et al., 1984; Torsethaugen et al., 1997; Elvira et al., 1998; Calzada et al., 2001), superoxide dismutase (Matters & Scandalios, 1987), glutathione (Madamanchi et al., 1991) and ascorbate (Castillo et al., 1987; Calzada et al., 2001; Van Hove et al., 2001). In contrast, Polle et al. (1993) found a significant decrease in superoxide dismutase activity for *Picea abies*. Foyer & Mullineaux (1994), Kangasjärvi et al. (1994) and Heath & Taylor (1997) published excellent reviews on detoxification processes in plants.

If the plant is not able to detoxify the different reactive species, the plasma membrane loses its functions, such as permeability, membrane fluidity, K<sup>+</sup>-exchange etc., which leads to a loss of transport ability of chemical substances and a loss of ionic homeostasis (Heath & Taylor, 1997; Skärby et al., 1998). Furthermore, dissolution products of O<sub>3</sub> entering the cell might initiate a decline in RUBISCO levels with negative effects for the rate of photosynthesis and productivity (the maximum assimilation rate is proportional to the amount of available RUBISCO linked to the energy produced by electron transport (v. Caemmerer & Farquhar, 1981; Heath & Taylor, 1997)). In fact, an ozone-induced decline of photosynthesis has been proved experimentally for instance by Wallin et al. (1990) for Norway spruce, McKee et al. (1995) for wheat, Farage & Long (1995) for pea, oak and wheat and Kellomäki & Wang (1997a,b) for Scots pine. Farage et al. (1991) and Farage & Long (1999) furthermore stress that often a decline in photosynthesis is an early symptom of an O<sub>3</sub> effect, even before visual damage occurs. Good reviews on changes in photosynthesis and related physiological processes due to air pollution have been published by Darrall (1989) and Saxe (1991).

In addition, there is evidence that exposure to O<sub>3</sub> is able to induce (partial) stomatal closure (e.g. Moldau et al., 1990; Grandjean Grimm & Fuhrer, 1992; McKee et al., 1995; Kellomäki & Wang, 1997; Van Hove et al., 2001), probably by directly affecting the guard cells or the mesophyll (Martin et al., 2000), which might as well reduce the plant's productivity (A/Ci-curves precisely indicate the relationship between

assimilation rate and  $g_s$ ). A positive relationship between (decreased) net photosynthesis and (decreased)  $g_s$  after  $O_3$  exposure was found for example by Hill & Littlefield (1969) for oats, Wallin et al. (1990) for young shoots of Norway spruce, Farage & Long (1995) for pea, oak and wheat, Mikkelsen (1995) for beech, Torsethaugen et al. (1997) for tobacco, Anderson et al. (1997) for Ponderosa pine and Elvira et al. (1998) for Aleppo pine.

These findings are the basis of several widely used models (e.g. Ball et al. 1987; Leuning, 1995; Martin et al., 2000), which predict  $g_s$  from the net photosynthetic rate.

However, there are concerns about this procedure which have to be addressed: Firstly, several authors stress that although there is a similar behaviour of  $g_s$  and net photosynthetic rate after exposure to  $O_3$ , this doesn't necessarily mean that there is a strong mechanistic relationship between these two parameters. Mikkelsen (1995), Farage & Long (1995) and Kellomäki & Wang (1997a) for instance found - based on the analysis of  $A/C_i$  curves - that a decrease in net photosynthetic rate was not due to a lower  $g_s$ , but to a decrease in biochemical processes of photosynthesis independent of  $g_s$ . Secondly, there is evidence that a decline in  $CO_2$  fixation is not necessarily linked to a simultaneous reduction of  $g_s$  and vice versa. In fact, a decoupling of  $g_s$  and photosynthesis has been shown for Douglas fir by Van Hove & Bossen (1994) (exposure to  $O_3$  reduced net  $CO_2$  assimilation but increased  $g_s$ ), for aspen clones by Yun & Laurence (1999a) (exposure to  $O_3$  significantly reduced net photosynthesis but not  $g_s$ ) and for wheat by Müller et al. (2005). The reason for this observation might be the more pronounced light saturation for net photosynthesis in comparison to  $g_s$  at certain developmental stages of the plant (Müller et al., 2005). A comprehensive overview of the mechanistic relationship between  $g_s$  and photosynthesis can be found in Farquhar & Sharkey (1982).

### ***1.2.2 Ozone-induced visible injury***

Several types of visible injury after O<sub>3</sub> exposure have been reported (cf. reviews by Heath, 1980 and Chappelka & Samuelson, 1998). The injury varies widely in its appearance between species (Table 1.1) and with the developmental stage of plants (cf. Heath, 1994; Pääkkönen et al., 1995). However, the most common injury symptoms have been described as bronzing (mainly on the adaxial leaf surface), chlorosis (from flecking up to large-scale inter-veinal chlorosis), necrosis (mostly flecking) and formation of anthocyanin (Koukol & Dugger, 1967; Jacobsen & Hill, 1970; Sanders & Benton, 1995, Flagler, 1998). Guderian et al. (1985) suppose that visible symptoms can be classified according to chronic or acute O<sub>3</sub> exposure, which causes different forms of damage reflecting different defence strategies of the plants: While leaf necrosis often occurs after short-term exposure to very high O<sub>3</sub> concentrations, chlorosis and bronzing is usually associated with chronic O<sub>3</sub> stress of much lower O<sub>3</sub> concentrations. Disbalances in the redox-status, ROS-production in the chloroplast stroma and a decrease of the chlorophyll-concentration (which leads to a discolouration of the leaf) causes a typical chlorosis (Schraudner et al., 1997), whereas a necrosis appears due to extracellular production of ROS and the destruction of the chlorophyll-rich palisade cells (Guderian et al., 1985; Borriss & Libbert, 1985). There is evidence that chlorosis caused by chronic exposure is reversible, whereas plants cannot recover from necrotic injury (Heath, 1987).

There is a vast variety of papers dealing with ozone-induced visible injury on crops, trees and semi-natural vegetation. Table 1.1 gives an overview of some of these papers without claiming to be complete. In summary, some agricultural crops usually react fastest to O<sub>3</sub> exposure, which makes them ideal indicators for active biomonitoring studies.

However, although visible injury has been established as a parameter for the identification of O<sub>3</sub> sensitivity, its assessment is highly dependant on the knowledge of the evaluator. In fact, chlorosis and necrosis are usually associated with many different types of stresses, and it requires coloured pictorial atlases (Sanders & Benton, 1995; Flagler, 1998) and comprehensive biomonitoring experience to distinguish leaf injury caused by O<sub>3</sub> exposure from injury caused by other stresses. Furthermore, different environmental conditions may alter the development of ozone-induced injury.

## 1. Introduction

Table 1.1 Selection of crop, tree and semi-natural vegetation species that exhibited ozone-induced visible injury. The table includes information on the type of experiment, the reported visible injury symptoms and the source.

Species	Field-grown (f)/ Potted (p)	Chamber study (yes/ no)	Type of reported visible injury	Source
<b>Agricultural crops</b>				
<i>Citrullus lanatus</i> (Watermelon)	f	n	From chlorotic mottle to necrotic brown-red spots (adaxial)	Decoteau et al. (1986)
	p	y & n	Purple stippling and necrosis	Gimeno et al. (1999)
<i>Glycine max</i> (Soybean)	p	n	Necrosis and bronzing on upper leaf surface	Benton et al. (2000)
<i>Lycopersicon esculentum</i> (Tomato)	f	y	Light tan upper surface flecking and premature senescence	Temple (1990)
	p	y	Chlorotic flecking followed by necrotic patches	Hassan et al. (1999)
<i>Nicotiana tabacum</i> (Tobacco)	p & f	?	Dark lesions tending to bleach after exposure to sun	Heggestad (1991)
	p	y	White dots	Günthardt-Goerg (1996)
	p	n	Large-scale bronzing (mostly adaxial)	Ritter (1996)
<i>Phaseolus vulgaris</i> (French Bean)	p	y	Adaxial stippling	Miller & Davis (1981)
	p	n	Dark brown blemishes, mainly adaxial	Tonneijck (1983), Tonneijck & Van Dijk (1997a)
	p	y	Bronze mottling symptoms	Sanders et al. (1992a)
	f	y	Interveinal brown spots on upper leaf surface	Schenone et al. (1992)
	p & f	n	Necrotic stippling	Vandermeiren et al. (1995)
	p	n	Large-scale bronzing (mostly adaxial)	Büker (1997)
<i>Solanum tuberosum</i> (Potato)	f	y & n	Necrotic lesions on adaxial surface of leaves	Donnelly et al. (2001)
<i>Spinacea oleracea</i> (Spinach)	p & f	n	Oily areas, upward bent leaves, white spots in glazed areas	Ashmore (1984), Skärby (1984)
<i>Zea mays</i> (Maize, Corn)	p	y	Not specified	Deveau et al. (1987)

## 1. Introduction

<b>Trees and shrubs</b>				
<i>Alnus glutinosa</i> (Alder)	p	y	Brownish discolouration between 2 <sup>nd</sup> order veins	Günthardt-Goerg (1996)
<i>Betula pendula</i> (Europ. White Birch)	p	y	Light-green dots or bronze discolouration	Günthardt-Goerg (1996)
<i>Betula pendula</i> (Europ. White Birch)	p	y	Small brown necrotic flecks (stippling), adaxial	Pääkkönen et al. (1998)
	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001), Zhang et al. (2001)
<i>Carpinus betulus</i> (Hornbeam)	p	y	Dots and leaf discolouration	Günthardt-Goerg et al. (2000)
<i>Crataegus monogyna</i> (Hawthorn)	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003)
<i>Fagus sylvatica</i> (European Beech)	p & f	y & n	Yellowish-brown leaves with small brown necrotic spots	Baumgarten et al. (2000)
	p	y	Slight stippling to large necrotic areas	Clark et al. (2000)
	p	y	Dots and leaf discolouration	Günthardt-Goerg et al. (2000)
<i>Fraxinus excelsior</i> (European Ash)	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001), Zhang et al. (2001)
	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003), Novak et al. (2005)
<i>Picea abies</i> (Norway Spruce)	p	y	Increased chlorosis after 3yrs. of fumigation	Braun & Flückiger (1995)
<i>Populus nigra</i> / <i>Populus x euamericana</i> (Black Poplar (hybrids))	p	y	Light-green leaf tip or leaf rim	Günthardt-Goerg (1996)
	p	n	Yellowish stippling with subsequent large-scale chlorosis	Ritter (1996)
	p	y	Yellow discolouration and necrotic spots	Bortier et al. (2000b)
	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003), Novak et al. (2005)
<i>Populus tremuloides</i> (Aspen)	p	y	Bifacial black necrosis, followed by leaf abscission	Yun & Laurence (1999b)
<i>Prunus serotina</i> (Black Cherry)	p	y	Dots and leaf discolouration	Günthardt-Goerg et al. (2000)
	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001), Zhang et al. (2001)
<i>Rhamnus cathartica</i> (Buckthorn)	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001), Zhang et al. (2001)
<i>Salix alba</i> (White Willow)	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003)
<i>Salix viminalis</i> (Silky Osier)	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001)
<i>Tilia platyphyllos</i> (Linden)	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003)

## 1. Introduction

<i>Viburnum lantana</i> (Wayfaring Tree)	p	y & n	Chlorotic spotting, adaxial pigmented stippling, reddening	Vanderheyden et al. (2001), Zhang et al. (2001)
	p	y	Dark-coloured stipple or discoloration (reddening or bronzing)	Novak et al. (2003), Novak et al. (2005)

<b>Semi-natural vegetation</b>				
<i>Phleum pratense and alpinum</i> (??)	p	y	Necrotic lesions	Danielsson et al. (1999)
<i>Trifolium pratense</i> (Red Clover)	p	y	White-brown necrotic spots	Lüthy-Krause et al. (1989)
	p	y & n	Small discoloured spots, partly necrotic	Pihl Karlsson et al. (1995a)
<i>Trifolium repens</i> (White Clover)	p	y & n	Small necrotic flecks on the upper leaf surface	Becker et al. (1989)
	p	y	Chlorosis and/or necrosis	Heagle et al. (1993)
	p	y & n	Small discoloured spots, partly necrotic	Pihl Karlsson et al. (1995a)
	p	n	Necrotic, point-shape yellow-whitish flecking	Büker (1997)
<i>Trifolium subterraneum</i> (Subterranean Clover)	p	y & n	Small discoloured spots, partly necrotic	Pihl Karlsson et al. (1995a)
	p	n	Chlorotic and bifacial necrotic spots	Pihl Karlsson et al. (1995b)
	p	y & n	Chlorotic and necrotic lesions on leaf surface	Pihl Karlsson et al. (2003)
27 Swedish native herbs and grasses	p	y	Necrotic or reddish flecks on 3 grasses	Pleijel & Danielsson (1997)
24 grassland species of Swiss Arrhenatheretalia plant communities	p	y	Small white-yellow flecks, dark necrotic flecks, leaf discoloration from dark-brown to reddish	Bungener et al. (1999a)
25 herbaceous plant species of arable field margins or disturbed habitats	p	y	Small whitish stipples, whitish flecking, necrotic spots	Bergmann et al. (1999)

### ***1.2.3 Growth and yield reduction***

Not all plants respond with characteristic visible injury after being exposed to O<sub>3</sub>, as has been shown for instance for some cereals (Hill & Littlefield, 1969; Pleijel, 1999). Instead, they might age more rapidly (also known as premature senescence) which has a negative effect on growth and yield.

The determination of growth and yield reductions is considered a more objective method to quantify the effects of O<sub>3</sub> on plants in comparison with the assessment of visible injury. This method directly measures the loss of plant material after the plant's exposure to O<sub>3</sub>. In addition, this response parameter has been proved valuable for deriving dose-response functions, provided that data on O<sub>3</sub> concentration is available. In combination with market prices, dose-response functions enable the calculation of economic losses, which makes this response parameter interesting as a basis for policy measures (Rosendahl & Hansen, 2000).

Often - but not always (see above) - growth and yield reductions are associated with leaf foliar injury, i.e. leaf necrosis might indicate oxidative cell damage, which leads to a reduced photosynthesis, followed by a growth reduction and finally a yield reduction. In other words, yield reductions are usually the result of a reduced plant growth, caused by a decrease of foliar chlorophyll content, reduced photosynthetic activity, altered photosynthate allocation and/or accelerated leaf senescence (Zelitch, I., 1982; Reich & Amundson, 1985).

Growth and yield reductions have been reported for several crops, tree and semi-natural vegetation species. Table 1.2 gives an overview of some growth and yield related experiments without claiming to be complete. Suitable parameters indicating growth and yield reductions vary from species to species, but the most common ones are relative growth rate (Evans, 1972), (total) biomass, fresh and dry weight, 1000 grain weight (cereals) and root to shoot biomass ratio. The latter is a good indicator for ozone-induced alterations in the carbon allocation of a plant, as has been shown by Reiling and Davison (1992) for several native herbaceous species, by Matyssek et al. (1992, 1993) for birch and poplar, by Paludan-Müller et al. (1999) for beech and Landolt et al. (2000) for beech and ash (however, Landolt et al. (2000) did not find changes in the root/shoot ratio for Norway spruce and Scots pine).

In contrast, some studies have shown no or very little effect of O<sub>3</sub> on some of the above mentioned growth parameters (e.g. Samuelson et al. (1996) → biomass of mature *Quercus rubra*; Novak et al. (2003) → no visible injury on *Clematis* ssp.; Pihl Karlsson et al. (submitted) → relative growth rate of *Trifolium pratense*) or even a yield stimulation following the plant's exposure to lower (ambient) concentrations of O<sub>3</sub>. For instance, Sanders et al. (1992b) found a higher yield for *Phaseolus vulgaris* exposed to 7 h mean O<sub>3</sub> concentrations of 32 ppb relative to the control treatment, Bungener et al. (1999) reported a significant ozone-induced stimulation of relative growth rate for *Centaurea jacea* and *Lychnis flos-cuculi* after the first season and a significant biomass increase for *Silene dioica* after the second growing season, Pleijel & Danielsson (1997) found a significant growth stimulation after exposure to O<sub>3</sub> for *Festuca ovina*, and Karlsson et al. (1997) proved a biomass stimulation for a slow-growing clone of *Picea abies* after exposure to non-filtered air plus 30 ppb O<sub>3</sub> for approx. 6 weeks.

Despite these examples of ozone-induced growth stimulations, it has to be stressed that the usual effects of O<sub>3</sub> on plants are detrimental.

## 1. Introduction

Table 1.2 Selection of crop, tree and semi-natural vegetation species that showed growth and/or yield reductions following O<sub>3</sub> exposure (AA = ambient air; NF = non-filtered air; RGR = relative growth rate, EDU = ethylenediurea, GP = growth periods).

Species	Field-grown (f)/ Potted (p)	Chamber study (yes/ no)	Reported growth and/or yield reduction after plant's exposure to ozone	Source
<b>Agricultural crops</b>				
<i>Brassica napus ssp. oleifera</i> (Winter Oilseed Rape)	f	n	8% decrease in plant dry weight and reduced root growth after exposure to daily mean O <sub>3</sub> concentration of 77 ppb for 32 days	Ollerenshaw et al. (1999)
<i>Citrullus lanatus</i> (Watermelon)	p	y & n	Yield loss of up to 39% after exposure to ozone	Gimeno et al. (1999)
<i>Glycine max</i> (Soybean)	f	y	Growth reduction up to 37%	Reich & Amundson (1985)
	p	y	1.5 × ambient O <sub>3</sub> concentration reduced seed yield by 41%	Fiscus et al. (1997)
<i>Lycopersicon esculentum</i> (Tomato)	f	y	Reduced yield by 17 to 54% for different cultivars after exposure to 1.5 times ambient O <sub>3</sub> concentration	Temple (1990)
	p	y	Final yield reduction of 31% for 80ppb O <sub>3</sub> treatment (13 weeks)	Reinert et al. (1997)
	p	y	Yield reduction of 48% for 68 ppb O <sub>3</sub> treatment (75 days)	Hassan et al. (1999)
<i>Nicotiana tabacum</i> (Tobacco)	p	y	Significantly reduced dry weight of leaves & roots after exposure to O <sub>3</sub> (150ppb, 4 h per day) for 2 weeks	Faensen-Thiebes (1983)
<i>Phaseolus vulgaris</i> (French Bean)	p	y	41% reduction in plant dry weight in NF + 20ppb O <sub>3</sub> treatment	Sanders et al. (1992a)
	p	y	26-42% yield reduction in high O <sub>3</sub> treatments (38, 45 & 50 ppb)	Sanders et al. (1992b)
	f	y	Significant reductions in yield after exposure to NF air	Schenone et al. (1992)
	p & f	n	14% pod yield reduction after exposure to ambient O <sub>3</sub> conc.	Vandermeiren et al. (1995)
	p	n	Enhanced dry pod yield by use of EDU → O <sub>3</sub> effect	Tonneijck & Van Dijk (1997a)
	p	y	Biomass and pod yield decreased with increase of O <sub>3</sub> conc.	Tonneijck & Van Dijk (1998)

## 1. Introduction

<i>Solanum tuberosum</i> (Potato)	f	y	Reduced stomatal conductance and yield as well as premature senescence after elevated O <sub>3</sub> exposure in OTCs	Pleijel et al. (2002)
	f	y & n	Reduced above-ground biomass and tuber dry weight after elevated O <sub>3</sub> exposure in OTCs or in FACE facilities	Craigon et al. (2002)
	f	y	Reduced above-ground dry weight by 8.4% after O <sub>3</sub> exposure	Lawson et al. (2001)
<i>Triticum aestivum</i> (Wheat)	f	y	Growth reduction up to 60%	Reich & Amundson (1985)
	f	y	Grain yield decreased with increasing seasonal mean O <sub>3</sub> conc.	Fuhrer et al. (1992)
	f	y	Smaller kernels, decreased 1000-grain weight after O <sub>3</sub> exposure	Ojanperä et al. (1998)
	f	n	Decreased above ground biomass after exposure to 80ppb O <sub>3</sub>	Ollerenshaw & Lyons (1999)
	f	y	Relative yield as low as 0.7	Pleijel et al. (2000)
	p	y	Significant reduction in 1000-grain weight after O <sub>3</sub> exposure	Meyer et al. (2000)
<i>Vitis vinifera</i> (Grape)	p	y	Reduction of 90% in grape and sugar yield after 3 yrs exposure	Soja et al. (2004)
<i>Zea mays</i> (Maize, Corn)	p	y	Reduced dry weight in 150 ppb O <sub>3</sub> treatment	Deveau et al. (1987)
<b>Trees</b>				
<i>Acer saccharum</i> (Sugar maple)	p	y	Root dry mass reduced by 10% in shaded plants	Tjoelker et al. (1993)
<i>Alnus glutinosa</i> (Alder)				
<i>Betula pendula</i> (Europ. White Birch)				Matyssek et al. (1992)
	p	y	Reduced growth rate of sensitive clone after O <sub>3</sub> exposure	Pääkkönen et al. (1998)
<i>Fagus sylvatica</i> (European Beech)	p	y	O <sub>3</sub> exposure (46.3 ppm h) reduced new growth by 17 %	Pearson & Mansfield (1994)
	p	y	Signific. reduction in mean biomass for 50% AA + 30 ppb O <sub>3</sub>	Clark et al. (2000)
	p	y	Significant decrease in biomass with increasing AOT40	Landolt et al. (2000)
<i>Fraxinus excelsior</i> (European Ash)	p	y	O <sub>3</sub> -drought interaction caused decrease in RGR of 32.8%	Reiner et al. (1996)
	p	y	Significant decrease in biomass with increasing AOT40	Landolt et al. (2000)
<i>Picea abies</i> (Norway Spruce)	p	y	Reduced rate of biomass increase in fast growing clone	Karlsson et al. (1997)
	p	y	8% biomass decrease after 4 growing seasons	Karlsson et al. (2002)

## 1. Introduction

	p	y	5% biomass decrease after 4 growing seasons	Ottosson et al. (2003)
<i>Pinus sylvestris</i> (Scots pine)	p	y	Significant decrease in biomass with increasing AOT40	Landolt et al. (2000)
	p	n	Slight decrease in current-year shoot growth	Utriainen & Holopainen (2000)
<i>Populus nigra</i> (Black Poplar)	p	y	Signific. reduction in growth rate after O <sub>3</sub> exposure (NF + 30 ppb O <sub>3</sub> )	Bortier et al. (2000b)
<i>Populus tremuloides</i> (American Aspen)	p	y	Plants smaller and with lower RGR for elevated O <sub>3</sub> treatment	Volin et al. (1998)
<i>Quercus rubra</i> (Red Oak)	p	y	Plants smaller and with lower RGR for elevated O <sub>3</sub> treatment	Volin et al. (1998)
<b>Semi-natural vegetation</b>				
<i>Calluna vulgaris</i> (Heather)	p	y	Reduced root dry weight by 22.5% in winter (not in summer)	Foot et al. (1996)
<i>Phleum pratense and alpinum</i> (??)	p	y	Significant reduction of biomass after exposure to elevated O <sub>3</sub>	Danielsson et al. (1999)
<i>Plantago major</i> (Greater Plantain)	p	y	Reduction in total weight after exposure to O <sub>3</sub>	Pearson et al. (1996)
	p	y	Total dry weight reduced by 35% after O <sub>3</sub> exposure for 56 days	Lyons & Barnes (1998)
	p	y	Reduction in biomass & no. of seeds per plant for O <sub>3</sub> treatment	Zheng et al. (2000)
<i>Trifolium pratense</i> (Red Clover)	f	y	Increasing O <sub>3</sub> -induced yield loss with time (2 yrs, 9 GP)	Fuhrer et al. (1994)
<i>Trifolium repens</i> (White Clover)	p	y	O <sub>3</sub> significantly decreased total weight of ozone-sensitive clone	Heagle et al. (1993), Heagle & Miller (1996)
	f	y	Increasing O <sub>3</sub> -induced yield loss with time (2 yrs, 9 GP)	Fuhrer et al. (1994)
	f	n	Significant effect of ozone on yield	Wilbourn et al. (1995)
	p	n	Dry matter production significantly lower in sensitive clone	Postiglione et al. (2000)
	p	y & n	O <sub>3</sub> significantly decreased biomass of ozone-sensitive clone	Bermejo et al. (2002)
	p	y	Significant decrease in RGR after exposure to O <sub>3</sub>	Pihl Karlsson et al. (submitted)
<i>Trifolium subterraneum</i> (Subterranean Clover)	p	n	Increased leaf biomass production by use of EDU → O <sub>3</sub> effect	Tonneijck & Van Dijk (1997b)
	p	y	O <sub>3</sub> -induced biomass reduction for limited period of plant's life-span	Sild et al. (1999)
	p	y	Significant decrease in RGR after exposure to O <sub>3</sub>	Pihl Karlsson et al. (submitted)
24 grassland species of Swiss Arrhenatheretalia plant communities	p	y	Decrease in biomass (partly significant) of 9 species	Bungener et al. (1999b)

### 1.3 The use of white clover (*Trifolium repens*) as an active bioindicator

In order to get an overview of the status quo and future trends of the emission and deposition of gaseous air pollutants in Germany (as in most industrialised countries), different national and local authorities (Umweltbundesamt, Landesumweltämter, Deutscher Wetterdienst) run monitoring networks at selected sites representing different landscapes, climates, altitudes and political regions.

Usually the equipment of the sites only allows for chemo-physical measurements of pollutants, which help to define pollutant climates over time. Although these concentration measurements have reached a high level of accuracy, they fail to give an indication of potential negative effects of air pollutants on plants. Therefore, the networks are from time to time complemented by bio-monitoring techniques, which are often run by universities or local authorities. By using living organisms, so-called bioindicators, these experiments aim to define the phytotoxicity of the prevailing pollution climate. Dependent on the target pollutant, the bioindicators are divided into accumulation and reaction bioindicators, with O<sub>3</sub> requiring the latter type. Furthermore, there is a distinction between passive and active bioindicators, reflecting the use of plants growing in their natural environment or plants that were cultivated in the greenhouse and then exposed to prevailing air pollutants according to a standardised protocol, respectively (Arndt et al., 1987; Arndt, 1992). Accordingly, the experiment carried out for this thesis has to be classified as an active reaction bio-monitoring.

Most of the recent German bio-monitoring experiments were embedded in large-scale, international research projects, such as the ICP Vegetation<sup>1</sup> (cf. ICP Vegetation, 2004; WGE, 2004) and the EuroBionet (Klumpp et al., 2002). The former has been using white clover clones for its Pan-European O<sub>3</sub> bio-monitoring experiment since 1996 (cf. chapter 4.2).

---

<sup>1</sup> ICP Vegetation: International Cooperative Programme on Effects of Air Pollution on Natural Vegetation and Crops

The history of using white clover for O<sub>3</sub> bio-monitoring experiments both in the USA and Europe goes back to 1989, when Becker et al. for the first time described typical ozone-induced foliar injury as necrotic lesions on white clover. Ever since, several research teams have used this plant to assess the phytotoxic capacity of O<sub>3</sub>, including Heagle et al. (1991, 1993, 1994, 1995, 1996), Fuhrer et al. (1993), Ashenden et al. (1995), Pihl Karlsson et al. (1995a), Wilbourn et al. (1995), Heagle & Miller (1996), B ker (1997), Chevone et al. (1998), Schulze (1999), Tang et al. (1999), Heagle & Stefanski (2000), Bermejo et al. (2002) and Pihl Karlsson (2003).

#### 1.4 Regulation of stomatal conductance

The cuticles of most higher plants build an effective barrier for gases to leave or enter the plant, which leads to the stomata being the prime site for gas exchange. In fact, the amount, distribution, size and shape of the stomata, all of which are species-specific, define the rate of incoming and leaving CO<sub>2</sub> as well as water vapour. One of the main challenges of plant life is the regulation of the stomata, which is critical for the balance between carbon gain and water loss, i.e. the balance between sufficient CO<sub>2</sub> uptake for photosynthetic processes and optimal rates of water vapour exchange to prevent life-threatening excessive transpirational losses (cf. Larcher, 1994).

The stomata are in constant movement, because they sensitively react to changes of the leaf-surrounding microclimate. The stomatal function, mediated by the difference in turgor pressure between highly specialised stomatal guard cells and their surrounding cells, is mainly dependent on environmental variables such as light (usually expressed as photosynthetic active radiation (PAR) when referring to plant physiological processes), external CO<sub>2</sub> concentration, air temperature, vapour pressure deficit (VPD), soil water status and wind (Jones, 1992).

There is an exponential increase in the stomatal diffusive resistance ( $r_s$ ) with decreasing width of the stomatal pores (cf. Jones, 1992). The inverse of  $r_s$  is the stomatal conductance ( $g_s = 1/r_s$ ), which is linearly proportional to the pore aperture. The  $g_s$  – whose prediction is the main scope of this study – provides an accurate quantification of gas fluxes, including gaseous pollutants, into the plant.

Since  $g_s$  is mainly driven by the above listed environmental variables, the rate of  $g_s$  varies over the course of a day (diurnal variation) as well as over the course of a growing season (seasonal variation). During the night, stomata are traditionally believed to be mostly shut, although significant rates of night-time  $g_s$  have been reported (e.g. Snyder et al., 2003). However, the maximum  $g_s$  is definitely achieved during day-time light-saturated growing conditions of plants with non-limiting (low) rates of VPD and soil moisture deficit (SMD). These optimal conditions are rarely met, but close-to-maximum  $g_s$  rates of  $C_3$  plants grown in Central Europe are usually reported at fairly warm and humid summer days.

In this thesis,  $g_s$  will be mainly predicted from the meteorological variables air temperature, VPD and PAR. The soil water status was not considered to be a main driver for  $g_s$  of the white clover clones used in this thesis, because the potted clover plants were kept well-watered throughout the growing season.

### 1.5 Aims and hypothesis

The aim of the work presented in this thesis was to develop a  $g_s$  model for white clover (*Trifolium repens*) based on measured climate, pollution and gas exchange data with the help of artificial neural networks (ANNs), and to use this model for the derivation of flux-response relationships for this species. The framework of the study is depicted in the flow-chart in Figure 1.4.

The following hypotheses were tested in this thesis:

- artificial neural networks (ANNs) are a useful tool for the development of a  $g_s$  model for white clover based on measured environmental data;
- the developed models predict realistic diurnal and seasonal rates of  $g_s$  for white clover when being applied to measured environmental time-series data;
- realistic diurnal and seasonal rates of  $O_3$  fluxes to white clover can be predicted with the help of the developed  $g_s$  models;
- the use of the flux-based AFstX index leads to better dose-response relationships for white clover when compared with the concentration-based AOT40 index;
- the different sensitivity of the ozone-resistant and ozone-sensitive white clover clone can be explained by the higher  $g_s$  of the latter;

- the white clover clone bio-indicator system is a useful tool for the assessment and quantification of effects of ambient  $O_3$  on crops and semi-natural vegetation.

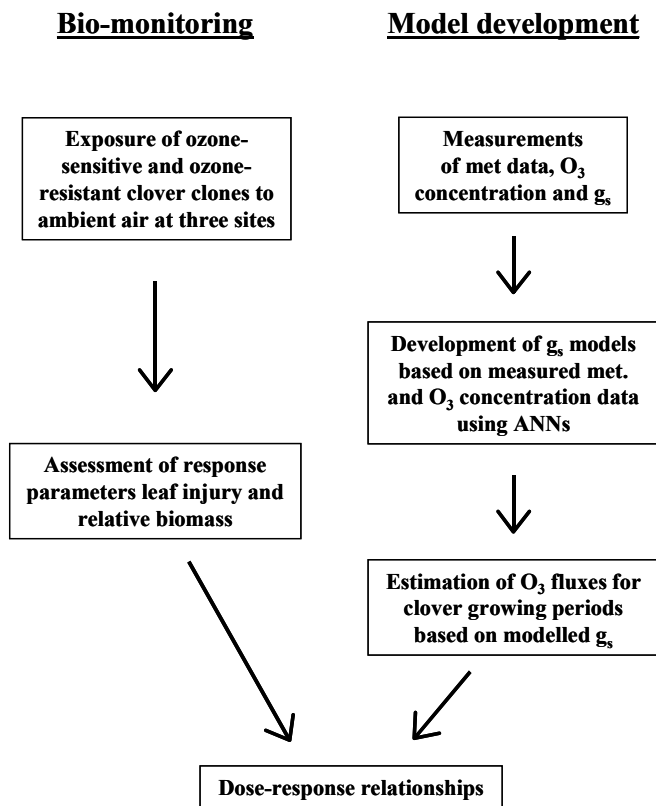

Figure 1.4 Flow-chart of framework of this thesis.

## **2 Past and present applications of artificial neural networks in natural sciences – an overview**

There is a general agreement among scientists that ideal models for predicting plant-atmosphere relationships should be mechanistic (explanatory) rather than (semi-) empirical models. However, such ideal models do not exist. In fact, mechanistic models predicting for instance the gas exchange between the plant interior and its direct environment would be extremely complex as well as time-intensive to develop and to run and therefore remain wishful thinking up-to-date and for the near future.

We have to realize that for many ecological phenomena – most of them are systematically based on highly non-linear relationships between several biotic and/or abiotic parameters – explanations in a mechanistic form are not (yet) available and probably not even necessary. The plant's function addressed in this thesis – i.e. the O<sub>3</sub> uptake via the stomata – is a good example for a very complex phenomenon for which a truly mechanistic explanation does not exist so far. Consequently, we are still dependent on empirical modelling approaches predicting the O<sub>3</sub> uptake of plants.

Traditionally, several statistic techniques, such as multiple linear regression and discriminant analysis, have been used for the quantification and prediction of plant-environment relationships. However, most plant-atmosphere relationships show a highly non-linear behaviour, which makes the use of techniques based on correlation coefficients often inappropriate. This is the main reason, why in recent years Artificial Neural Networks (ANN) have become a very popular tool for environmental modellers. It has been shown that ANNs are suitable in situations where the underlying relationships are non-linear (Lek et al., 1996b; Olden & Jackson, 2002) or even poorly known at all (Lek & Guégan, 1999).

In this chapter a brief history of ANNs will be given, followed by a review of recent ANN-applications in the environmental sciences, a detailed description of a typical feed-forward ANN trained by backpropagation (the most frequently and in this thesis used type of ANNs) and a list of methods to potentially invalidate the “black box” criticism. The development, interpretation and validation of the ANN's used in this thesis are described separately in Chapter 6.

### 2.1 History of artificial neural networks

When computers were initially developed, they were only able to cope with serial problems, i.e. problems that could be solved step by step in a logical sequence. However, the need for understanding and predicting non-linear phenomena made a further development of computers necessary. The idea was that computers should have the skills to solve parallel problems analogous to the function of the human brain that is able to cope with highly complex tasks such as recognition of faces or wise reactions to threats.

First attempts to simulate the human brain in computer technology are known from the 1940s. For instance, McCulloch and Pitts (1943) developed simple artificial neurons, which in retrospect have to be recognised as initial steps in the history of artificial intelligence (AI). In the following, these neurons were connected with each other, which for the first time created artificial neural networks (ANNs). Early applications of ANNs aimed at analysing biological phenomena such as the mammalian brain function (Lek & Guégan, 1999; Olden et al., 2004).

The main criticisms/disadvantages of the early networks were that they required very complex algorithms and that there was no possibility to weigh the links between input and output. The psychologist Frank Rosenblatt started in the 1950's to overcome this problem by developing the so-called "perceptron model" which consisted of two layers of neurons connected by a single layer of weighted links (Rosenblatt, 1962). The calculations of the output values of this network were based on the weights of the interconnecting neurons. Though this model of weighted networks was further developed in the 1960's (Minsky & Papert, 1969), its main drawback, i.e. the inability to alter the weights during the training process, remained which resulted in limited use of the perceptron model.

The subsequent period of stagnation in the development of ANNs was overcome in the late 1970's/early 1980's when several research groups realised that much more complex, multi-dimensional problems could be tackled using ANNs by introducing multiple layers of perceptrons. Typically, these multiple layer perceptrons consisted of three layers of neurons with adjustable weights of the interconnecting neurons (Rumelhart & McClelland, 1986).

One of the major remaining problems for multilayer networks was to find an adequate algorithm to account for global minima in the error function. Although already developed in the late 1970's, it was not until the mid 1980's that Rumelhart and colleagues (1986) presented the backpropagation training algorithm to a wider research public. Since then, this is the most frequently – and as well in this thesis - used training algorithm.

Beside the multi-layer backpropagation ANNs, various other types of neural networks have been developed, such as the Hopfield network (Hopfield, 1982), Kohonen network (Kohonen, 1982, 1984) and the Boltzmann machine (Ackley et al. 1985). The choice of the network depends on the nature of the problem to be solved. Today, ANNs are able to give satisfactorily answers to questions of auto-associative memory, generalisation, optimisation and data reduction, control and prediction. The latter mentioned ability is the main reason for using ANNs in this thesis.

## **2.2 Application of artificial neural networks in ecological and environmental sciences**

The obvious improvements of ANNs since the late 1980s/early 1990s on the one hand and the further software development and the availability of suitable hardware (e.g. parallel computers and analogue/digital neural cards for personal computers) on the other hand led to an exponentially grown interest in ANNs. In 1992, the world market for the commercial use of ANNs had expanded to be in the order of tens of million dollars and was at that time predicted to be in the range of approximately \$5 billion by 2000 (Hubick, 1992).

Scientists from various research fields, such as graphology, psychology, economy, medicine, physics, ecology etc. considered the use of ANNs for different reasons. Successful applications have been reported for replicate tasks like handwritten character recognition (Yeung & Fong, 1994), speech recognition (Rahim et al., 1993; Chu & Bose, 1998), texture recognition (Tirakis et al., 1990; Rangarajan et al., 1991), face recognition (Cottrell & Fleming, 1990), image recognition (Dekruger & Hunt, 1994; Cosatto & Graf, 1995; Kung & Taur, 1995), spectral recognition (Wythoff et al., 1990),

cell classification (Bazoon et al., 1994), chromosome classification (Lerner, 1994) and two-dimensional shape classification (Khotanzad & Lu, 1991).

Furthermore, the predictive ability of ANNs convinced many scientists to favour this tool over standard statistical techniques. Examples of successful predictions with the aid of ANNs have been published in the field of medicine (Burke et al., 1995; Lo et al., 1995; Orr, 1995), economics (Schöneburg, 1990; Refenes et al., 1993; Hoptruff, 1993; Tan et al., 1995) and physics (Chakraborty et al., 1992).

Some early applications of ANNs in ecological and environmental sciences were reported at the beginning of the 1990s (e.g. Colasanti, 1991). Since then, a steadily increasing number of scientists in these fields, especially environmental modellers, focussed on testing the ability of ANNs as a tool for analysing and predicting complex non-linear ecological phenomena.

ANNs are known for being very powerful in dealing with non-linear relationships (Lek et al., 1996b), which makes them an ideal tool for bringing light into the usually very complex relationships between ecological variables. In fact, in direct comparison with traditional statistical model approaches based on regression analyses, ANNs have shown a higher prediction ability (e.g. Baran et al., 1996; Paruelo & Tomasel, 1997; Ramos-Nino et al., 1997; Starett & Adams, 1997; Manel et al., 1999; Özesmi & Özesmi, 1999).

Since the early 1990s, an increasing number of scientists have shown the strengths and advantages of ANNs in very different fields in applied ecology and environmental science. For instance, De Silets et al. (1992) predicted sea water salinity with the help of ANNs, Daniell & Wundke (1993) used ANNs to estimate water nutrient concentrations, Seginer et al. (1994) modelled the greenhouse effect, Edwards and Morse (1995) stressed the potential of ANNs in biodiversity research, Smith and Eli (1995) assessed the rainfall-runoff, Lek et al. (1996 a,b) and Baran et al. (1996) predicted various parameters in brown trout management, Brey et al. (1996) modelled the production/biomass ratio of animal populations, Poff et al. (1996) assessed the effect of climate change on river hydrology and ecology, Roadknight et al. (1997) and Pastor-Bárcenas et al. (2005) predicted surface O<sub>3</sub> concentrations, Tangang et al. (1997)

modelled sea surface temperatures, Goswami & Srividya (1996) and Zhang et al. (1997) used ANNs to estimate rainfall, Van Wijk & Bouten (1999) modelled water and carbon fluxes above European coniferous forests and Karul et al. (2000) modelled eutrophication processes of large water bodies in Turkey.

In plant sciences, ANNs have increasingly been used since the mid 1990s. Hirafuji & Kubota (1994) determined effects of various stresses on photosynthesis, Scardi (1996), Recknagel et al. (1997) and Whitehead et al. (1997) modelled algal concentrations, Balls (1996), Ball et al. (1998, 2000) and Mills et al. (2000) identified factors which influenced the effects of ambient O<sub>3</sub> on white clover, Maier & Dandy (1997) assessed the incidences of blue-green algae, Barciela et al. (1999) predicted phytoplankton production and Bungener et al. (1999) used ANNs to analyse the injury response of nine grassland species to O<sub>3</sub>.

In this thesis ANNs will be used to predict O<sub>3</sub> fluxes to white clover plants in dependence on the environmental parameters air temperature, photosynthetic active radiation (PAR) and vapour pressure deficit (VPD).

The ANN software used in this thesis is NeuroShell 2 (Ward Systems Group Inc., USA). It has been successfully applied to identify non-linear relationships of ecological phenomena for instance by Balls (1996), Roadknight et al. (1997), Ball et al. (1998, 2000), Ryan et al. (2004) etc. The features of this software package and the development of the model will be presented in Chapter 6.

### **2.3 Backpropagation artificial neural networks**

Multi-layer feed-forward artificial neural networks trained by backpropagation algorithm, also known as backpropagation neural networks or single/multi-layer perceptron, is the most commonly used type of networks today, because it has proved to be a powerful method for modelling complex relationships between variables. This was the reason for also applying it in this thesis.

The purpose of these networks is to capture the relationship between a set of model inputs and corresponding outputs. This procedure is called supervised learning. In other words, backpropagation networks develop models only from the data presented, which

together are assumed to implicitly contain the information necessary to establish relations between different input and output parameters by determining the weighted connections between them. Therefore, backpropagation neural networks allow the prediction of output variables for given input variables.

The architecture of a backpropagation neural network consists of three different layers called input, hidden and output layer (Figure 2.1). There can be more than one hidden layer and hidden layers can also be split up into different parallel functioning sub-layers in order to apply different activation functions (see Chapter 6.1) in parallel during model runs. The three types of layers contain one or more interconnected non-linear processing elements, called neurons (Hecht-Nielsen, 1990). The number of neurons in the input layer matches the number of input (independent) variables, whereas the number of neurons in the hidden layer is usually varied – using the trial and error method - during the model training process in order to find the optimal predictive performance of the model. The output layer comprises as many neurons as there are target (dependent) variables.

During the training of the neural network, the internal information or signal “flows” from the input through the hidden layer to the output layer. This happens by connecting all input neurons to all hidden neurons by weighted links, i.e. each input neuron is multiplied by the weight of the connection (Figure 2.1). This weight can be positive or negative. Negative connection weights represent inhibitory effects on neurons (i.e. reducing the intensity of the incoming signal) and decrease the value of the predicted response, whereas positive connection weights represent excitatory effects on neurons (i.e. increasing the intensity of the incoming signal) and increase the value of the predicted response.

Typically a non-linear activation function, e.g. Gaussian, logistic or hyperbolic tangent, is then fed with the sum of the weighted inputs. This process creates a value that is compared with the actual output value. The resulting error value, which is based on the difference between these two values, is in the following returned (or backpropagated, which explains the name of this type of ANNs) in a loop to the hidden neurons and multiplied by an adjusted weighting factor.

Figure 2.1 Architecture and operation of a typical backpropagation neural network with one hidden layer (after Maier & Dandy, 1998);  $X_i$  = output from previous layer,  $W_{ji}$  = weight of interconnection  $j$  between neuron  $i$  and current neuron.

In general, the neurons of the hidden and output layer are stimulated by the neurons of the previous layer according to the following relationship:

$$a_j = \sum_{i=1}^l X_i W_{ji}, \quad (2.1)$$

where  $a_j$  is the activation of the  $j^{\text{th}}$  neuron,  $X_i$  the output value of the  $i^{\text{th}}$  neuron of the previous layer and  $W_{ji}$  the synaptic weight of the connection between the  $i^{\text{th}}$  neuron of the previous layer and the  $j^{\text{th}}$  neuron of the current layer.

The adjustment of the interconnections of the neurons is done repeatedly in order to minimize the output error. The amount by which each connection weight is adjusted depends on the learning rate ( $\eta$ ) and the momentum value ( $\mu$ ). These two parameters serve to accelerate the training while preventing the network from falling into local minima (Baran et al., 1996).

The momentum term has the effect of adding a proportion of the previous weight change to the current weight change during the training process. The proportion of the previous weight change added is equal to the momentum,  $\mu$ . The momentum ensures that general trends are reinforced and oscillatory behaviour is suppressed. The momentum value must be less than 1.0 for convergence (Dai & Macbeth, 1997). Generally, high momentum values are suggested for noisy datasets.

The learning rate  $\eta$  is proportional to the amount a particular connection weight is changed during one epoch (i.e. a complete pass through the network) of the training procedure (cf. Viotti et al., 2002). It is multiplied by the error of the network and its value can vary in the range of 0 to 1. Usually it is set close to zero, because high values (i.e. close to 1) might lead to large oscillations during the training process or – in the worst case – might suppress convergence of the network at all. However, very small learning rates slow down the learning of the network.

This shows the problem of finding the optimal learning rate and momentum for the network. Similar to the decision on the optimal number of used hidden neurons, this problem is usually solved by trial and error.

The above mentioned output error is calculated by the so-called error or performance function. Usually, the output error is defined by either the sum or the mean of the squared differences between the predicted and given (typically measured) output values. Maier and Dandy (1998) have shown that the use of the sum of squared errors, also called the quadratic error function, resulted in a faster learning speed and better generalisation ability of the network in comparison with other error functions. In fact, the ANN software used in this thesis (NeuroShell 2) uses by default the sum of squared errors (SSE) to determine the output error:

$$\text{SSE} = 1/2 \sum_{i=1}^N (Y_i - \hat{Y}_i)^2 \quad (2.2)$$

where  $N$  is the number of elements,  $i$  is the index of elements,  $Y_i$  is the desired (measured) value for the  $i^{\text{th}}$  element and  $\hat{Y}_i$  is the calculated or predicted value for the  $i^{\text{th}}$  element. In theory, one could run the training until the output error does not decrease further. However, this procedure would almost certainly lead to an over-trained network.

Symptomatic for an over-trained (or over-fitted) network is its poor generalisation ability, i.e. the network predicts the output very well when using the dataset it was trained with, but very badly when using a new dataset. This shows that one of the biggest problems in creating a good prediction model is the decision when to stop the training procedure. If the training is stopped too early, the network might not have learned the data patterns properly which might result in a low predictive ability of the network. In contrast, if the training is stopped too late (or if too many hidden neurons have been used), neural networks tend to learn the noise in the data and memorise training patterns instead of interpolating between them, which limits the generalisation with new patterns (like mentioned above).

To overcome this problem, the network should be constantly compared to an initially extracted subset of the data during the training. This subset, in the following called test set, is randomly excluded from the training dataset before the start of the training. It is therefore not used for the computation of the connection weights but for calibrating the network and eventually stopping the training at a certain point. This happens by reading in the test set at intervals the modeller defines and comparing the predicted output value

of the training set with the output values of the test set using the sum of the squared errors like described above. The training should be stopped, when this sum of squared errors is at its minimum.

Once this minimum value is reached, the connection weights remain fixed and the neural network can be used for predictions. Provided the training data was fully representative of the entire data range of each input variable, the network will then be able to accurately predict the output for random data combinations of input variables. In order to test this, a second subset of the training set can be extracted before the start of the training, the so-called (cross-)validation set. This set contains data the network has never “seen” before and therefore gives an insight in the real generalisation and prediction ability of the network.

Finally, it has to be stressed that any data ANNs are applied to should always be in the same range like the data with which the network was trained with to assure satisfactory prediction results, because ANNs have very limited extrapolation abilities.

#### **2.4 Illuminating the “black box”**

As mentioned above, ANNs have been successfully used in various different research fields and there is little contradiction that they are an attractive, non-linear alternative to traditional statistical methods. Although it is obvious that ANNs are well suited for developing prediction models (e.g. Baran et al., 1996; Paruelo & Tomasel, 1997; Ramos-Nino et al., 1997; Starett & Adams, 1997; Manel et al., 1999; Özesmi & Özesmi, 1999), there has always been a lot of criticism about the explanatory ability of ANNs. In fact, they have often been considered as being a “black box” approach to modelling ecological phenomena (e.g. Lek & Guégan, 1999; Özesmi & Özesmi, 1999). The reason for this is based on the fact that the contribution of each input variable in predicting the output is difficult to identify, an effect that is increasing with increasing numbers of hidden neurons. Especially in ecological sciences, where the aim of most studies is gaining insight into causal relationships of ecological phenomena, this fact is considered as a big drawback. Furthermore, it is - with the exception of very trivial networks - usually not possible to give the equation of the network code because of the complexity of the internal structure of ANNs.

Unfortunately, this lack of clear, easily understandable relationships between input and output variables make ANN-based models often unpopular among stakeholders, politicians and even researchers. Hence, this fact has to be seen as the major disadvantage of ANNs in comparison with traditional statistical methods.

However, quite a few papers have been published recently giving overviews and performance rankings of methods to enlighten the relationships between input and output variables and general internal processes of ANNs (e.g. Özesmi & Özesmi, 1999; Olden & Jackson, 2002; Gevrey et al., 2003; Olden et al., 2004). Among these methods the most common are:

- i) Pruning algorithms for eliminating irrelevant input (e.g. Bishop, 1995; Maier et al., 1998; van Wijk & Bouten, 1999); this method excludes variables and/or neuron interconnections that are below a pre-defined threshold. By doing this, the network is reduced to a potentially more interpretable size.
- ii) Partial derivatives method (e.g. Dimopoulos et al., 1995, 1999); this method computes the partial derivatives of the ANN output with respect to the input variables. As a result, a profile of the output variations for small changes of each input variable and a classification of the relative contributions of each variable to the network output are obtained.
- iii) Sensitivity analysis (e.g. Lek et al., 1996 a, b; Özesmi & Özesmi, 1999; Olden et al., 2002); traditionally, this method varies each input variable across its entire range while holding all other input variable constant. It gives a good indication of the relative importance of single variables on the dependent variable.
- iv) Garson's algorithm (e.g. Garson, 1991; Goh, 1995; Gevrey et al., 2003; Olden & Jackson, 2002); this method partitions the hidden-output connection weights into components associated with each input neuron using absolute values of connection weights in order to determine the relative importance of the various inputs in the network.
- v) Connection weight approach (e.g. Olden & Jackson, 2002; Olden et al., 2004); this method calculates the product of the raw input-hidden and hidden-output connection weights between each input neuron and output neuron and sums the product across all hidden neurons.

In this thesis, the sensitivity analysis, the connection weight approach and an internal NeuroShell 2 weighting analysis tool have been used (cf. Chapter 6.2), all of them for different reasons: the sensitivity analysis gives a good visual indication of the importance of each input variable on the output variable (which is only a qualitative tool, though), the connection weight approach showed very good results in several studies and proved to be better than Garson's algorithm (e.g. Olden & Jackson, 2002; Olden et al., 2004), while the NeuroShell 2 analysis weighting tool was just practical to use since it was always quickly available. The connection weight approach is basically also a kind of manual pruning tool as it clearly identifies those variables that only marginally contribute to the prediction of the output.

In summary, these different methods can help "illuminating the black box" (Olden & Jackson, 2002). By using a combination of quantitative approaches, such as the connection weight approach, and qualitative/visual approaches, such as neural interpretation diagrams (cf. Özesmi & Özesmi, 1999) and sensitivity analysis, it is now possible to identify and interpret individual and interacting contributions of the input variables in neural networks. Therefore, Olden and Jackson (2002) argue that because of the variety of above mentioned methods to enlighten the internal working of neural networks it is not appropriate anymore to call ANNs "black boxes".

### 3 Material and methods

#### 3.1 Geographical classification of the natural landscapes of the Trier region and location of experimental sites

The ambient air bio-monitoring experiment of this thesis was conducted at three sites in the Trier region. The West German city of Trier (population approx. 108.000) is located in the German federal state of Rhineland-Palatinate (SW-Germany). The city centre has been built in the valley of the river Mosel, whereas many suburbs, including Tarforst with its University campus, are located on former river terraces north and south of the current river valley floor. The Trier region is a typical German midrange mountain area with several plateaus separated by river and creek valleys. The plateaus are used for forestry (mainly coniferous plantations) and agriculture (cultivation of cereals, dairy farming), whereas the slopes of the valleys are characterized by either little woods or groves (often deciduous trees) or viticulture. The main river, Mosel, separates the low mountain ranges of the “Eifel” and “Hunsrück”, both part of the “Mittel-Rheinisches Schiefergebirge”.

Figure 3.1 Transect showing the location of the field sites Trier-City, Trier-University and Deuselbach, and a map indicating the position of Trier in relation to Germany’s national territory.

Due to Trier's vicinity to the Atlantic Ocean, the climate of the region has to be considered predominantly as oceanic with relatively humid, cool summers and mild winters (Closs, 1979). Mostly westerly winds bring an average yearly rainfall of approx. 750mm. The heterogeneous distribution of precipitation in the region is dependent on the high relief energy, which separates the landscape in windward and leeward areas with highly differing precipitation amounts.

The three experimental sites selected for the bio-monitoring were named "Trier-City", "Trier-University" and "Deuselbach". The urban site Trier-City was located on the premises of the "Städtisches Gartenbauamt" (49°45'26"N, 06°38'38"E; 129 m a.s.l.), the sub-urban site Trier-University on the premises of the University of Trier (1997 to 1999: Floristic garden of the Department of Geobotany, 49°44'56"N, 06°41'10"E; 255 m a.s.l. – after that (2000 and 2001) relocation to a new campus approx. 500 meters north of the initial location: 49°44'55"N, 06°40'29"E; 259 m a.s.l.) and the rural site Deuselbach on the premises of the "Messstelle Deuselbach" (49°45'47"N, 07°03'18"E; 480 m a.s.l.) of the Umweltbundesamt (Figure 3.1).

### 3.2 Plant material and its propagation

Two clones of white clover (*Trifolium repens* L. cv. Regal) with different sensitivity to O<sub>3</sub> were selected for this experiment: the ozone-sensitive NC-S clone and the ozone-resistant NC-R clone (Figure 3.2). Each clone is genetically uniform and was originally cultivated by Al Heagle (cf. Heagle et al., 1991, 1995) in North Carolina (therefore the abbreviation NC-S and NC-R) in the 1980's. His research team collected field-grown white clover for duplication/multiplication and reproduced it vegetatively (asexual) in the greenhouse to maintain the genetic information of the initial "mother plant". The new plants, grown from cuttings of the "mother plant", were then exposed to high concentrations of O<sub>3</sub> in open top chambers (OTCs) in order to identify the most and least ozone-sensitive plants. Subsequently, these most and least ozone-sensitive individuals were again reproduced as described above and again exposed to O<sub>3</sub>. This step was repeated several times and finally resulted in the establishment of the ozone-sensitive NC-S and ozone-resistant NC-R clones of identical genetics each.

Figure 3.2 Photos of typically round-shaped and oval-shaped leaves of the ozone-resistant (NC-R, left) and ozone-sensitive (NC-S, right) white clover clones (*Trifolium repens* L. cv. Regal), respectively.

Over the last 20 years, these clover clones (Figure 3.2) have been frequently used for O<sub>3</sub> bio-monitoring experiments both in the USA and Europe (cf. Chapter 2.2.4). The satisfactory results of the clover clone system was a main reason for the ICP Vegetation<sup>1</sup> to introduce this bio-indicator system for its Pan-European O<sub>3</sub> bio-monitoring experiment in 1996, which has been performed during all growing seasons ever since.

Another reason for selecting *Trifolium repens* as a bioindicator for a Pan-European survey was the wide spatial distribution of this species in Europe, ranging from Scandinavia to the Mediterranean and from the Atlantic to the Ural Mountains (the distribution map of the genus *Trifolium* (Figure 3.3) gives an indication of the vast circumpolar presence of species of this genus). In fact, white clover is an important and often dominant species in several grassland communities in Europe, which therefore is of high economical interest, too. Furthermore, the regenerative growth of white clover after a harvest is very quick, which is an important precondition for the experimental approach used in the ICP Vegetation.

The Department of Geobotany of the University of Trier joined the ICP Vegetation in 1996 and used the above described clover clones for the first time in 1997 and in the

---

<sup>1</sup> ICP Vegetation: International cooperative programme on effects of air pollution on natural vegetation and crops

following years until present. The participation in this bio-monitoring network offered the opportunity to use the clover clone plants for additional, more detailed experiments, which form the basis of this thesis.

Figure 3.3 Terrestrial spatial distribution of the genus *Trifolium* (Gillet, 1985)

The plant material was always supplied by the Coordination Centre of the ICP Vegetation at CEH Bangor (Centre for Ecology and Hydrology). Virus-free white clover clone cuttings of 7-10 cm length with 3-4 leaf nodes were sent via express delivery from Bangor to Trier. After arrival, cuttings were immediately planted into 1-litre pots in a non-filtered air greenhouse. The pots contained a fertilized peat substrate (TKS 2) and were positioned under mercury-vapour lamps, which supplemented the natural light throughout the daylight hours (i.e. between approx. 7 a.m. and 8 p.m.). All plants were watered regularly, depending on weather conditions. At day 10, 20 ml of a rhizobium-water slurry was added as a soil drench to all plants to initiate the mycorrhizal symbiosis, which is beneficial for the nitrogen fixation in Fabaceae (such as *Trifolium*). In addition, on day 21 after planting all plants were fertilised with 150 ml of a water solution containing 1 g/litre of Peters 5-11-26 (N-P-K) nutrient solution.

At day 28 after planting, all cuttings were transplanted into bigger pots with a volume of 15 litres and a diameter of approx. 30 cm (Figure 3.4). The used substrate was a 1:1:1 mixture of local sterilised soil, peat (TKS 2) and sand, enriched with approx. 60 g of slow release (5 months) fertilizer Osmocote<sup>®</sup> (N:P:K → 14:13:14) per pot. In order to maintain a constant water supply and to prevent water stress, all pots were equipped

with five fibre-glass wicks leaving the bottom of each pot via five holes. This system allowed a capillary water transport whenever the plants were in need of water from water reservoirs (buckets) positioned under the planting pots (Figure 3.4).

Figure 3.4 Schematic illustration of a typical plant pot and its water reservoir underneath used in this study. The five black lines depict the glass-fibre wicks, which allowed a capillary water transport into the soil/plant.

### 3.3 Experimental design, meteorological recording and assessment methods

#### 3.3.1 Experimental design

The above described potted white clover clones were exposed to ambient air at the sites Trier-City, Trier-University and Deuselbach for 140 days (20 weeks) during the vegetation period of the years 1997 (pilot study), 1998, 1999, 2000 and 2001. Each year, 20 plants of each clone were exposed according to the experimental protocol of the ICP Vegetation (e.g. ICP Vegetation, 1998), which resulted in an experimental design of four rows containing ten pots. The NC-S and NC-R plants were arranged alternately as shown in Figure 3.5. In order to prevent the black planting pots and reservoirs from over-heating, aluminised bubble-wrap was placed around them.

Furthermore, the experimental site was kept free from weed by initially covering it with a black plastic, woven planting foil. Figure 3.6 shows a typical site set-up (shown site: Deuselbach).

During the exposure time, a careful observation for insect pests was required. Especially aphids – though rarely - tended to attack the plants and were therefore treated with the insecticide/pesticide 'Spruzit' (4 % Pyrethrine, 16 % Piperonylbutoxid; Neudorff Chemicals). This was especially necessary in 1998 and 1999. In addition, slugs had to be controlled using slug pellets (Mesurool, Bayer Chemicals), whereas herbivore (e.g. rabbits) attacks were prevented by erecting a rabbit-proof fence around the experimental site.

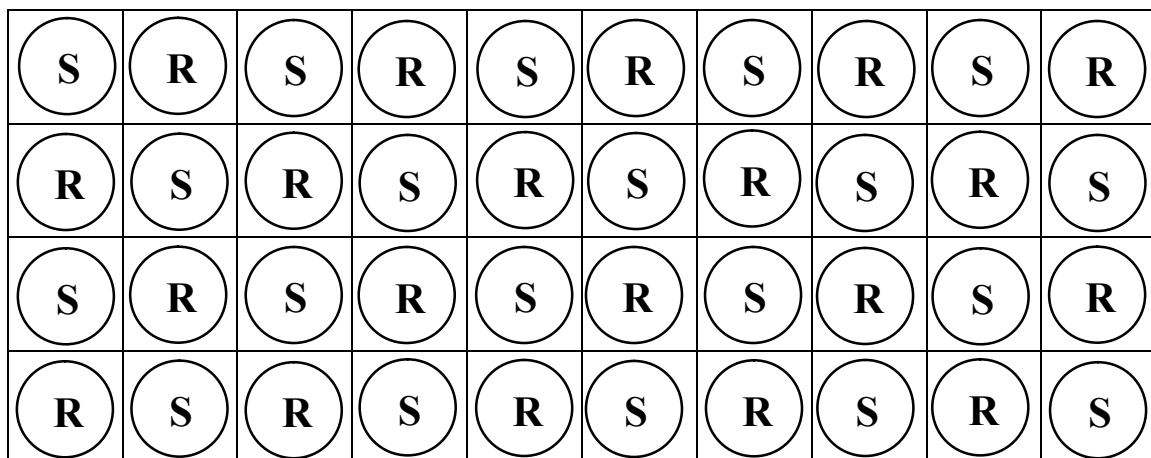

Figure 3.5 Experimental design of the clover bio-monitoring experiment (S = NC-S clone, R = NC-R clone).

Figure 3.6 Typical site set-up showing four rows of potted clover plants in Deuselbach in 1998.

Another potential source of disturbance of the experiment were infections by viruses. Especially the resistant clover clone sometimes showed after weeks of exposure a large yellowish/whitish flecking on the leaves. Unfortunately, there are no chemicals to protect plants from viruses. Hence, plants showing virus infections even after cutting back the infected leaves were excluded from the experiment. However, this was only necessary in September 1998 (removal of two NC-R plants).

### 3.3.2 *Meteorological recordings*

In all years, meteorological parameters and the ambient O<sub>3</sub> concentrations were recorded in direct vicinity of the exposed plants at a standardised height of three meters above ground. The meteorological and O<sub>3</sub> concentration data for the site Trier-City were recorded at the weather station “Ostallee”, which is run by the federal state of Rhineland-Palatinate. All parameters were recorded half-hourly, but all data were transformed to hourly means prior to their use in this thesis.

At the site Trier-University, air temperature [°C], global radiation [W\*m<sup>-2</sup>], relative humidity [%], wind speed [m/s], wind direction [°] and rainfall [mm] were measured in 1997, 1998 and 1999 with the own meteorological station (EcoTech, Messsysteme, Bonn, Germany) of the Department of Geobotany, which was positioned in the floristic garden of the department. The measuring system was always calibrated in springtime prior to its use from May on. O<sub>3</sub> [µg\*m<sup>3</sup>] was simultaneously recorded using a Horiba O<sub>3</sub> analyser, which was calibrated annually in spring by cross-validating it with O<sub>3</sub> concentrations measured at the weather station “Deuselbach” of the Bundesumweltamt, as well as on a daily basis with the help of an on-site O<sub>3</sub> generator. All above-mentioned parameters were measured every 10 seconds, saved on a computer located nearby in the glasshouse and manually averaged for 60 minute intervals.

In the years 2000 and 2001, the same meteorological parameters were measured by the weather station of the Department of Climatology of the University of Trier, which was located next to the experimental site of the clover clone experiment. The O<sub>3</sub> concentration [ppb] was measured by the ZIMEN<sup>2</sup> measuring station, also located next to the experimental site. Again, hourly means were calculated for all parameters.

---

<sup>2</sup> ZIMEN = Zentrales Immissionsmessnetz des Landes Rheinland-Pfalz (Landesamt für Umweltschutz und Gewerbeaufsicht, 1978-2001).

The meteorological and O<sub>3</sub> concentration data for the site Deuselbach were recorded in the immediate vicinity of the bio-monitoring experiment on the premises of the weather station Deuselbach of the “Umweltbundesamt”. All parameters were recorded half-hourly, but as for the other sites, all data were transformed to hourly means prior to their use in this thesis.

For the model approach, the parameters photosynthetic active radiation (PAR), vapour pressure deficit (VPD) and AOT40 (accumulated concentrations above a threshold of 40 ppb) were required. These parameters could be easily derived from the measured parameters mentioned above by using the following equations (v. Willert et al., 1995):

$$\text{VPD [hPa]} = e^{\circ} - e \quad (3.1)$$

where  $e^{\circ}$  is the saturation water vapour pressure and  $e$  is the water vapour partial pressure. According to Campbell & Norman (1998), the saturation water vapour pressure can be calculated with the following equation:

$$e^{\circ} = \exp(52.57633 - 6790.4985 / (273.15 + T) - 5.02808 * \ln(273.15 + T)) \quad (3.2)$$

where  $T$  is the air temperature [°C]. Subsequently,  $e$  can be calculated as followed:

$$e = \text{RH} * e^{\circ} / 100 \quad (3.3)$$

where RH is the relative humidity [%].

PAR was derived from measured global radiation (GR) data based on an empirical relationship detected prior to the main experiment (comparison of global radiation measuring device with PAR sensor of gas exchange measuring system) according to the following equation:

$$\text{PAR} [\mu\text{mol} * \text{m}^{-2} * \text{s}^{-1}] = 1.941 * \text{GR} [\text{W m}^{-2}] \quad (3.4)$$

The AOT40 was calculated according to the following equation:

$$\text{AOT40 [ppb.h]} = \Sigma ((\text{O}_3 \text{ concentrations} > 40 \text{ ppb for GR} > 50 \text{ W m}^{-2}) - 40) \quad (3.5)$$

### 3.3.3 Assessment and harvest methods

Visible injury was assessed at least once a week. The first occurrence of O<sub>3</sub> injury on the sensitive and resistant clone (usually white small flecking on leaves) after transplanting and each harvest (see below) was recorded. A more detailed visible injury assessment was done prior to the destructive harvest on each harvest day, i.e. five times per growing season (Table 3.1). First, each plant was graded as either healthy or abnormal, with the cause of the abnormality scored as 1 (slight), 2 (moderate) or 3 (severe) using the following classification:

Table 3.1 Classification of visible injury (ICP Vegetation, 1998)

Abbreviation	Type of abnormality
O	Ozone injury
S	Stunted
D	Diseased
I	Insect damage
Sl	Slug damage
A	Animal (rabbits, deer, birds etc.)
V	Virus

Subsequently, a scoring system - presented in Table 3.2 - developed by the ICP Vegetation (cf. ICP Vegetation, 1998) was used for the detailed visible O<sub>3</sub> injury assessment. Figure 3.7 shows two photos of a NC-S clover clone with an O<sub>3</sub> injury score of 1 and 4.

Table 3.2 Scoring system of visible O<sub>3</sub> injury assessment (ICP Vegetation, 1998)

Score	Extent of visible injury	Definition
0	No injury	No symptoms
1	Very slight injury	Occurrence of first symptoms
2	Slight injury	1-5 % of leaves with slight injury
3	Moderate injury	5-25% of leaves with injury
4	Heavy injury	25 - 90% of leaves with injury
5	Total injury	90-100 % of leaves with injury

Figure 3.7 Visible injury on the sensitive white clover clone (NC-S) after exposure to ambient air. Typical first injury symptoms expressed as white spots at the edge of the leaf (left) and heavy ozone-induced foliar injury (right) would correspond with injury class 1 and 4, respectively (cf. Table 3.2).

After the detailed visible injury assessment, a destructive harvest was carried out. The first harvest always took place four weeks after the plant transplantation and was repeated four times each year (Table 3.3 – 3.5). The forage (leaves, flowers and stolons) was harvested 7 cm above the soil surface by using long-blade scissors. Runners that grew outside the pot perimeter were harvested, too. Injured leaves that remained after cutting the above mentioned top 7 cm of the forage were removed in order to prevent confusion with new injury occurrence at subsequent observations. Furthermore, alcohol was used for disinfection of the scissors to prevent virus spread from plant to plant.

<b>Harvest 5</b>	30/09	05/10	20/09	02/10	08/10

The plant material was separated in leaves, flowers and stolons, before putting it in separate labelled paper bags. These bags were dried for 24 hours at 105° Celsius in an oven.

After drying, the dry weight of leaves, flowers and stolons was determined with a high precision scale. In order to get an indication about the impact of O<sub>3</sub> on plant health and plant productivity, the relationship of the biomass of the ozone-sensitive and the ozone-resistant clover clones was calculated (NC-S/NC-R-ratio). The idea behind this concept is that the ozone-induced growth inhibition due to a diminished photosynthesis is reflected by the difference between the biomass of the ozone-sensitive and ozone-resistant clover clone.

### 3.4 Stomatal conductance measurements

#### 3.4.1 *Description of the gas exchange measuring system*

The aim of this thesis was to develop a stomatal conductance model ( $g_s$ -model) based on meteorological, phenological and air pollution data in order to quantify the O<sub>3</sub> flux into leaves of clover clone plants. Therefore, measuring stomatal conductance ( $g_s$ ) was the key activity of the experimental part of this thesis.

Diurnal leaf gas exchange measurements were made using the portable photosynthesis system HCM-1000 (Heinz Walz GmbH, Effeltrich, Germany). The HCM-1000 is an “open system”, i.e. the ambient air is absorbed continuously. It consists of the central unit with an input buffer and an intake antenna, a climatized measuring cuvette, a CO<sub>2</sub> dosing unit (optional, not used for field measurements), a lighting unit (optional, not used for field measurements) and a palmtop computer (HP-200/H). The key part of the central unit builds an infrared gas analyser (IRGA, here: BINOS-100/4PS), which calculates the CO<sub>2</sub> and H<sub>2</sub>O concentration of the incoming airflow. The concentrations of these two gases are necessary to assess the net photosynthesis and transpiration rate. Apart from the gas analyser, the central unit consists of a manually operated valve for the H<sub>2</sub>O regulation, a pump, a small buffer vessel, a mass flow meter, two gas valves and a barometric air pressure sensor. Figure 3.8 shows the pneumatic components along the gas path of the HCM-1000.

Despite the fact that this machine uses a closed cuvette to measure the gas exchange of a defined leaf area of a leaf fixed in the cuvette, it is able to perform measurements under natural conditions by simulating the environmental conditions of the prevailing ambient air as precisely as possible in the climatized measuring cuvette.

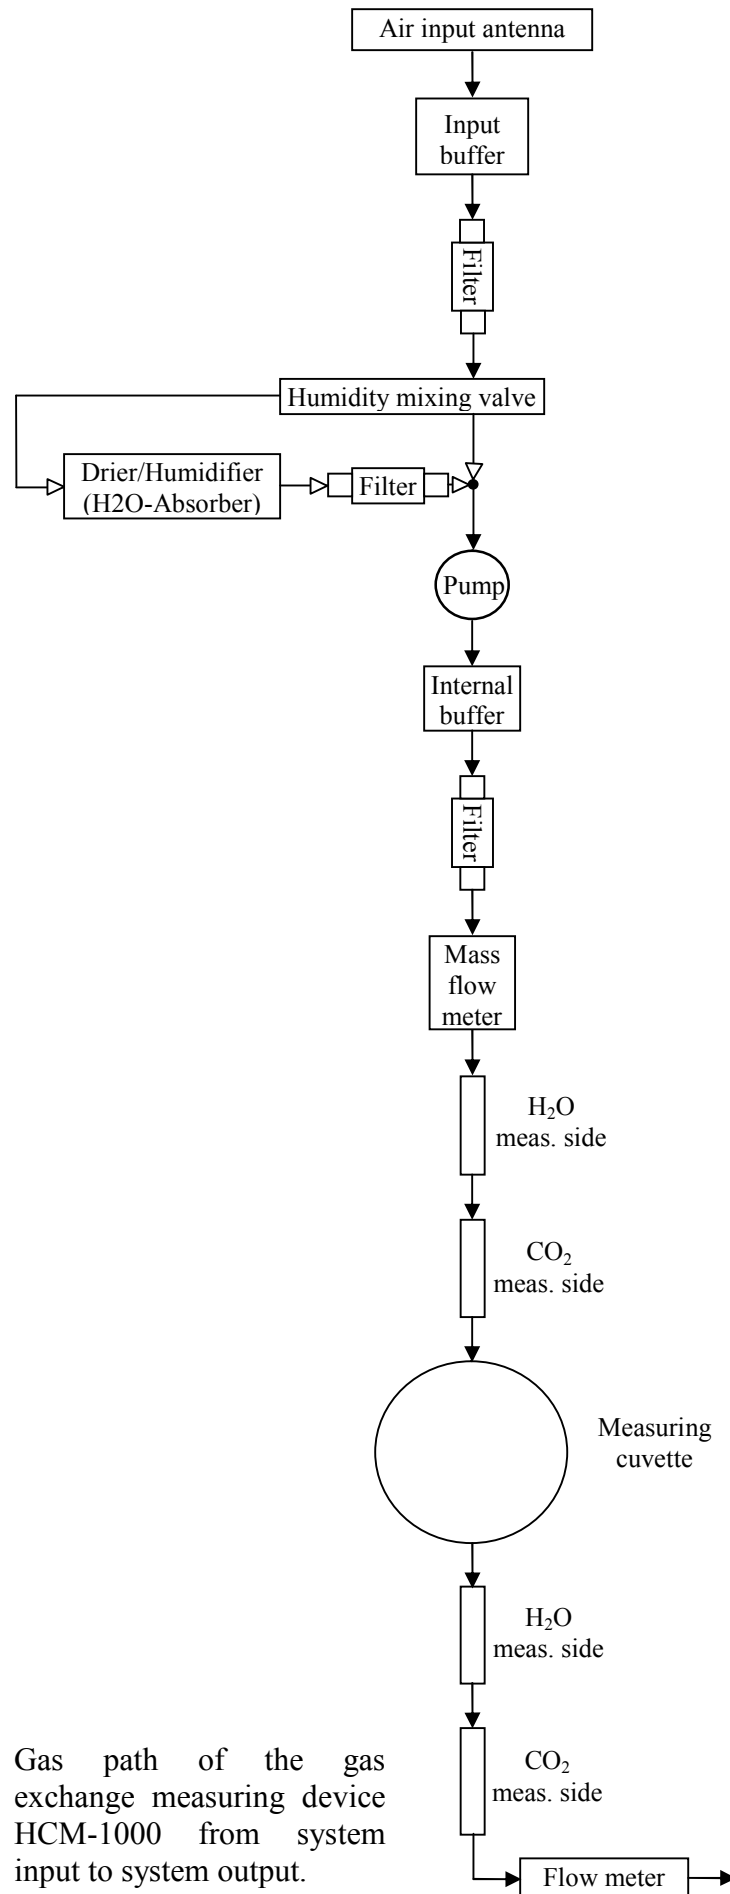

Figure 3.8 Gas path of the gas exchange measuring device HCM-1000 from system input to system output.

In fact, the temperature and relative humidity in the cuvette can track ambient air conditions. Furthermore, since the cuvette is transparent, the light conditions in it are similar to the ambient light conditions.

The measuring cuvette comprises several sensors for different meteorological parameters such as the photosynthetically active radiation, air temperature inside the cuvette, relative humidity inside the cuvette, leaf temperature and air temperature outside the cuvette.

The HCM-1000 was directly connected to a palmtop computer (HP-200/H) equipped with a 512kB EPROM card and a software (“DA-1000”) for recording and saving all measurements as well as calibrating the system. At the end of each measuring campaign, the measured data points were transferred from the palmtop to a personal computer.

#### ***3.4.2 Gas exchange measurements and the determination of stomatal conductance***

The above described gas exchange system (as well as all its competitors) is not able to measure the  $g_s$  and net photosynthetic rate directly. Instead, these two parameters have to be calculated from the directly measured difference of the  $H_2O$  and  $CO_2$  concentration of the incoming airflow before and after streaming through a measuring object (leaf). The operation mode of the gas exchange measurements and the subsequent determination of  $g_s$  (which is the key parameter for modelling  $O_3$  fluxes) will be briefly described in the following.

The BINOS 100/4PS gas analyser has two analyser cuvettes, one each for the above mentioned gases. Both cuvettes are separated in two halves, the measuring and the reference side. In order to assess a  $CO_2$  and  $H_2O$  measuring point (MP), the air flow is directed through the measuring side of the two analyser cuvettes first, before streaming through the measuring cuvette containing the enclosed measuring object (leaf) and subsequently streaming through the reference side of the analyser cuvette. This procedure is shown schematically in Figure 3.8. The measuring point taken represents the relative difference between the  $CO_2$  and  $H_2O$  concentrations of the airflow before and after streaming through the leaf enclosed in the measuring cuvette. However, for the

calculation of the rates of net photosynthesis and transpiration (and subsequently the  $g_s$  to water vapour), the absolute differences of these two gases before and after having streamed through the leaf ( $\Delta\text{CO}_2$  and  $\Delta\text{H}_2\text{O}$ , respectively) are needed. This requires - according to the following equation - the assessment of  $\text{CO}_2$  and  $\text{H}_2\text{O}$  zero points (ZP) and the base concentrations of the respective gas (C):

$$\Delta\text{CO}_2 = (\text{MP}_{\text{CO}_2} - \text{ZP}_{\text{CO}_2})/C_{\text{CO}_2} \quad (3.6)$$

and

$$\Delta\text{H}_2\text{O} = (\text{MP}_{\text{H}_2\text{O}} - \text{ZP}_{\text{H}_2\text{O}})/C_{\text{H}_2\text{O}} \quad (3.7)$$

The assessment of a zero point can be done by either leaving the measuring cuvette empty (no enclosed leaf) and progressing in the above mentioned manner (zero cuvette mode) or by changing the order of the analyser cuvettes (zero bypass mode), i.e. directing the air flow through both the measuring and reference sides of the analyser cuvettes first before entering the measuring cuvette. The latter method has the advantage that the enclosed leaf does not have to be removed from the measuring cuvette during the assessment of the zero point which predestines this method to be used during long-lasting (e.g. for several hours) measuring periods.

The stomatal conductance to water vapour ( $g_{\text{H}_2\text{O}}$ ) is calculated according to the following equation by v. Caemmerer and Farquhar (1981):

$$g_{\text{H}_2\text{O}} = E/\text{ALVPD} \quad (3.8)$$

where E is the transpiration rate and ALVPD the water vapour gradient between leaf and air.

The ALVPD is a function of the  $\text{H}_2\text{O}$  mole fraction within and outside the leaf with these two mole fractions being dependent on the total pressure in the measurement cuvette at a measurement point and on the saturated water vapour pressure at the leaf temperature and at the cuvette, respectively (for details see v. Caemmerer & Farquhar,

1981 and v. Willert et al., 1995). The saturated water vapour pressure again is temperature dependant and can be derived from tables (e.g. Walz, 1996).

According to v. Caemmerer & Farquhar (1981), the transpiration rate  $E$  [ $\text{mmol} \cdot \text{m}^{-2} \cdot \text{s}^{-1}$ ] can be calculated using the following formula:

$$E = \frac{u_e * (w_o - w_e)}{LA * (1 - w_o)} \quad (3.9)$$

where  $u_e$  is the molar flow at the inlet of the measuring cuvette (at a measuring point MP [ $\text{mmol} \cdot \text{s}^{-1}$ ]),  $w_o$  is the  $\text{H}_2\text{O}$  mole fraction at the outlet of the measuring cuvette [ppm],  $w_e$  is the  $\text{H}_2\text{O}$  mole fraction at the inlet of the measuring cuvette [ppm] and LA is the reference variable (here the leaf area in  $\text{cm}^2$ ). For calculating the two different mole fractions, see Jones (1992) or Walz (1996).

The term  $(w_o - w_e)$  represents the pressure dependant difference between a measurement point and a zero point:

$$(w_o - w_e) = (MP_{\text{H}_2\text{O}} - ZP_{\text{H}_2\text{O}}) * 1/h * P_{\text{norm}}/P_{\text{reference}} \quad (3.10)$$

where  $P_{\text{norm}}$  is the pressure on which the infrared gas analyser is normalised during the calibration (= 1013 hPa),  $P_{\text{reference}}$  is the total pressure inside the  $\text{H}_2\text{O}$  reference side of the gas analyser during a measuring point, and  $h$  is a sensitivity factor of the  $\text{H}_2\text{O}$  differential measurement, which is dependent on the  $\text{H}_2\text{O}$  basic concentration (dimensionless; for the derivation of  $h$  see Walz, 1996).

### 3.4.3 Description of the measuring programme

Prior to starting a measuring period, some parameters affecting the measurements had to be set and controlled. First of all, the use of an antenna guaranteed the intake of air masses at a height of three meters. This height was chosen because it corresponded with the height at which  $\text{O}_3$  concentrations were measured by the nearby ZIMEN-station (cf. Chapter 3.3.2). This height also ensured that the measurements were not disturbed by the respiration of the gas exchange system user. Furthermore, a 10L input buffer was

installed in order to prevent short-term and small fluctuations of the CO<sub>2</sub> concentration of the absorbed ambient air. Then the cuvette temperature, relative humidity and CO<sub>2</sub> concentration were set to track the conditions of the ambient air. Furthermore, the flow rate was always set to 800ml/min, a value recommended by the manufacturer of the gas exchange system. Lastly, the reference measuring area had to be defined. It was constant at 2.5 cm<sup>2</sup> for all measurements since the enclosed leaf always covered the entire measuring area (PLA = Projected Leaf Area) of 2.5 cm<sup>2</sup>.

At the start of a measuring day of usually several consecutive day-light hours, the gas exchange system was run for at least 20-30 minutes to give the gas analyser the required time to reach operating temperature and to give the entire system time to adapt to the prevailing ambient meteorological conditions. The measurements were started only after the signals for the CO<sub>2</sub> and H<sub>2</sub>O zero point remained constant in the measuring mode zero bypass.

First of all, measurements of the CO<sub>2</sub> and H<sub>2</sub>O base concentration had to be executed in order to provide real measured values for the subsequent measurements of the CO<sub>2</sub> and H<sub>2</sub>O zero points and the CO<sub>2</sub> absolute concentration, all of which were part of the following automated measuring series typically executed over the course of a day (only daylight hours, though). These series followed a predetermined format/pattern:

CA,5\*(10\*MP,ZB),CA,5\*....

This means that a series always started with a CO<sub>2</sub> absolute measurement (CA), followed by a measuring cycle (10-times a measuring point (MP) before setting a new bypass zero point (ZB)) that was repeated 5-times before starting the loop again with a CO<sub>2</sub> absolute measurement. The measuring signal for each measurement was averaged for 60 seconds, which resulted in one measuring point per minute or approximately 40 measurements per hour (the detection of bypass zero points and a CO<sub>2</sub> absolute measurement took approx. 20 minutes per hour).

All measurements were always carried out on the third or fourth leaf of a white clover plant, counted from the tip of the stolon. This not only minimised the variation in the

dataset by always using leaves of the same age, but was also believed to best represent the average gas exchange of the entire plant.

#### **3.4.4 Restrictions of the measurements**

In the early morning hours after sunrise, in the late evening hours before sunset and directly after rainfall events, the air is often highly water-saturated, which can cause problems for the detection of transpiration using gas exchange measuring systems like the HCM-1000. Precisely, absorbed humid air might lead to water vapour condensation inside the measuring cuvette, which affects the transpiration measurements for a longer time. This made measurements during above-mentioned climatic conditions impossible. Furthermore, since it is not possible to use the gas exchange systems during rainfall events, all measurements were carried out either during bright, partly cloudy or fully overcast weather conditions.

#### **3.5 Calculation of ozone fluxes to clover leaves**

In order to quantify the potential risk of O<sub>3</sub> to plants, the O<sub>3</sub> uptake rate of a plant, defined as the O<sub>3</sub> flux entering the plant per defined area and time, is calculated and accumulated over the course of the plant's exposure period. This accumulated O<sub>3</sub> uptake rate is then related to effect criteria such as biomass reduction and visible injury.

The stomatal flux algorithm used in this thesis is identical to the one suggested by the UNECE Mapping Manual (UNECE, 2004). It is based on the electrical analogue principle derived from Ohm's law (cf. Monteith and Unsworth, 1990). Assuming that the O<sub>3</sub> concentration at the top of a canopy is a reasonable estimate of the O<sub>3</sub> concentration at the boundary layer of a sunlit upper canopy leaf, the flux (F<sub>st</sub>, nmol m<sup>-2</sup> projected leaf area) can be calculated according to the following formula:

$$F_{st} = (O_{3(\text{can})} - O_{3(\text{int})}) * g_s * \frac{r_c}{r_b + r_c} \quad (3.11)$$

where  $O_{3(\text{can})}$  and  $O_{3(\text{int})}$  are the  $O_3$  concentrations at the top of the canopy and in the intercellular spaces of the leaves respectively,  $r_b$  the quasi-laminar resistance and  $r_c$  the leaf surface resistance.

$O_{3(\text{can})}$  was calculated from the  $O_3$  concentration measured at three meter at all experimental sites according to the neutral stability profile method described in detail in the Mapping Manual (UNECE, 2004). This method is dependant on wind speed measurements and requires the estimation of the deposition velocity ( $V_g$ ) as well as the aerodynamic ( $R_a$ ), canopy boundary layer ( $R_b$ ) and canopy ( $R_c$ ) resistance, all of which could be calculated from the available meteorological data. For details, see Mapping Manual (UNECE, 2004).

Laisk et al. (1989) have empirically shown that it is justifiable to assume that  $O_{3(\text{int})}$  is usually close to zero due to reactive sinks within a leaf, leading to the omission of this term in equation 3.11.  $r_c$  is given by

$$r_c = 1/(g_s + g_{\text{ext}}) \quad (3.12)$$

where  $g_{\text{ext}}$  is the cuticular (external) resistance. The Mapping Manual (UNECE, 2004) suggests a constant for the cuticular resistance of

$$g_{\text{ext}} = 1/2500 \text{ [m s}^{-1}\text{]} \quad (3.13)$$

whereas the quasi-laminar resistance is derived according to the cross-wind leaf ( $L$ ) dimension and the wind speed at the canopy height ( $u_{(\text{can})}$ ):

$$r_b = 1.3 * 150 * (L / u_{(\text{can})})^{0.5} \text{ [s m}^{-1}\text{]} \quad (3.14)$$

The factor 1.3 accounts for the difference in diffusivity between heat and  $O_3$ . To account for the well-fertilised white clover clone plants used in this thesis,  $L$  was set to 5 cm.

The central term of the flux algorithm is the  $g_s$ , which was modelled using artificial neural networks, the core task of this thesis. The models predict  $g_s$  for water vapour

( $g_{\text{H}_2\text{O}}$ ), which has to be converted into  $g_s$  for  $\text{O}_3$  ( $g_{\text{O}_3}$ ) for the flux calculations under consideration of the differences in molecular diffusivity between water and  $\text{O}_3$  ( $D_{\text{O}_3}/D_{\text{H}_2\text{O}} = 0.61$ ):

$$g_{\text{O}_3} = g_{\text{H}_2\text{O}} * D_{\text{O}_3}/D_{\text{H}_2\text{O}} \quad (3.15)$$

In the following, the term  $g_s$  is used when stomatal conductance in general is concerned, whereas specific references to  $g_s$  of water vapour or  $\text{O}_3$  are denoted as “ $g_s$  (mmol  $\text{H}_2\text{O}$   $\text{m}^{-2}$  PLA  $\text{s}^{-1}$ )” and “ $g_s$  (mmol  $\text{O}_3$   $\text{m}^{-2}$  PLA  $\text{s}^{-1}$ )”, respectively. PLA refers to the projected leaf area, the common scaling basis for  $g_s$  measurements.

### 3.6 Dose-response relationships

The clover dose-response relationships using flux- and concentration-based  $\text{O}_3$  indices are based on biomass and injury assessment data recorded at three sites at the end of each of four (growth periods 2 to 5) 28-day growth periods of the years 1997 to 2001 (cf. Chapter 3.3.3). The data of the first growth period were always omitted for this analysis, because they represent the usually hugely variable establishing period of the clover plants.

The biomass ratio of the two white clover clones (NC-S/NC-R) determined at each harvest was related to the respective 28-day i) AOT40 value calculated for single as well as combined growth periods and sites, ii) modelled accumulated fluxes with thresholds varying from 0 to 10  $\text{nmol m}^{-2} \text{s}^{-1}$  (AFst0-10) using the NC-S and NC-SR model and iii) ratio between modelled accumulated fluxes with various thresholds using the NC-S and NC-R ANN-based  $g_s$  model. Furthermore, the recorded biomass of both clones (as opposed to the ratio) was related to the respective AOT40 as well as the accumulated fluxes with various thresholds using the NC-S and NC-R model (i.e. biomass of NC-S and NC-R clones vs. AFstX predicted with the NC-S and NC-R models, respectively).

Linear regressions analyses (see chapter 3.7) were applied for the derivation of dose-response functions. These analyses were performed for each individual site and growth period, as well as for combined growth periods and sites.

### 3.7 Statistics

Common descriptive statistics were applied for the characterisation of the meteorological,  $O_3$  and  $g_s$  dataset. In order to analyse potential inter-correlations between different input parameters, a Spearman's rank-order correlation test (a non parametric test had to be used, because the  $g_s$  datasets of both genotypes were not normally distributed – see below) was carried out.

It was of high interest in this study whether or not it would be necessary and desirable to develop separate ANN-based flux models for each of the two white clover clones, which was decided upon the results of a test of statistical difference between the  $g_s$  data of both clones. The choice of the appropriate test was dependent on the outcome of the Kolmogorov-Smirnov test (K-S test) for normal distribution, which was applied to both NC-S and NC-R  $g_s$ -datasets prior to the test of difference. Due to the rejection of the hypothesis of normally distributed data, the nonparametric Mann-Whitney U-test had to be applied.

Furthermore, prior to the development of the ANN-based flux models for both clover clones, a stepwise (multiple) regression analysis of both  $g_s$  datasets was carried out to gain a first impression of the suitability of the chosen seven input parameters in explaining the variation in the observations of the output parameter  $g_s$ .

To analyse the performance of the ANN-based  $g_s$  models by comparing predicted with observed  $g_s$  rates, linear regressions were applied. The same statistical method was also used for the determination of dose-response relationships between response (i.e. clover biomass and visible leaf injury) and  $O_3$  exposure (accumulated AOT40) as well as  $O_3$  uptake (AFstX). All statistics were carried out using SPSS 10.

## 4 Climate of growing seasons 1997 to 2001 in the Trier region

The bio-monitoring experiment using white clover clones was carried out during 5-month growing periods from May to October in five consecutive years 1997 until 2001 at three field sites Trier-City, Trier-University and Deuselbach. The flux model developed in this study was applied to datasets consisting of hourly physical and pollution climate data, covering the complete five growing seasons of the clover bio-monitoring experiment.

In the following sections, each of these five growing seasons is described using i) time courses of the climate and O<sub>3</sub> concentrations of the five growing seasons expressed as daily means for air temperature [°C] and O<sub>3</sub> concentrations [ppb], daily minimum for air temperature and VPD [kPa] as well as daily maximum for air temperature, VPD and PAR [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ] (Figure 4.1 to 4.5), and ii) bar charts presenting the mean (+ 1 S.D.) of the meteorological parameters air temperature, VPD, PAR and wind speed [ $\text{m s}^{-1}$ ] as well as the mean annual O<sub>3</sub> concentration (Figure 4.6). More detailed figures and tables showing the variation of the climate between single growth periods and years can be found in Appendix A.

The clover plants were always kept well watered in order to prevent any water stress-induced limitations of g<sub>s</sub>. This meant there was no need to include a soil water parameter (e.g. soil water potential, soil moisture deficit etc.) as input for the flux model, and hence it was not necessary to include rainfall in Figures 4.1 to 4.6.

### 4.1 Seasonal differences in physical and pollution climate

In general, the seasonal time courses of air temperature are quite noisy, with some distinct peaks in excess of 25° C during almost all months between June and September in all five years. However, the general trend was an increase in temperature from May until July and August, when all sites experienced the highest (actual and average) air temperatures of up to 35 to 38 °C, followed by a decline towards the end of GP 5, i.e. end of September/beginning of October (Figures 4.1 to 4.5 and Appendix A). Minimum night temperatures were never below 1 °C, i.e. the plants never experienced any frost.

Since VPD is dependent on air temperature, the highest VPD-values were found also during GP 3 or GP 4, i.e. in July and/or August of each year (Figures 4.1 to 4.5, Appendix A). Maximum values of up to 5.5 kPa were recorded, but mean values for 28 days GPs were typically well below 1 kPa.

The same seasonal pattern was not reported for PAR, which showed an almost uniform – if rather scattered - distribution over the GP 1 to 4, with a decline starting during GP 5 (Figures 4.1 to 4.5). Maximum values of up to almost 2000  $\mu\text{mol m}^{-2} \text{s}^{-1}$  were usually reported during June (Appendix A), around solstice time. However, apart from during GP 5 in 2000 and 2001, there were no longer periods with PAR values below light saturation (approx. 1200  $\mu\text{mol m}^{-2} \text{s}^{-1}$ , cf. van Willert et al., 1995) during any of the GPs of all years (Figure 4.1 to 4.5).

Wind speed (Appendix A), which was included because of its influence in scaling down  $\text{O}_3$  concentrations from its measuring height to the plant canopy height, shows a relatively even distribution over the course of the growing season. Maximum values of up to 16  $\text{m s}^{-1}$  were reported for different months of the growing seasons. However, depending on the field site, average 28 days values of wind speed never exceeded 5  $\text{m s}^{-1}$  (maximum mean value of 4.71  $\text{m s}^{-1}$  for GP 5 in Deuselbach, 2001; Appendix A).

The seasonal time courses of the  $\text{O}_3$  concentration are – similar to the time courses of air temperature – quite scattered (Figures 4.1 to 4.5), with growing season (i.e. 5 consecutive GPs) hourly maximum values of between 65 and 110 ppb reached at different months in the years 1997 to 2001 (Appendix A). However, concentrations tended to decline towards the end of GP 5 (Figures 4.1 to 4.5, Appendix A). It should be pointed out that episodes of high  $\text{O}_3$  concentration normally lasted for two to three days.

Figure 4.1 Time course of the climate and  $\text{O}_3$  concentration at the sites Trier-City (top), Trier-University (middle) and Deuselbach (bottom) during the 1997 growing season, expressed as daily mean (air temperature,  $\text{O}_3$  concentration), daily minimum (air temperature, VPD) and daily maximum (air temperature, VPD, PAR).

Figure 4.2 Time course of the climate and O<sub>3</sub> concentration at the sites Trier-City (top), Trier-University (middle) and Deuselbach (bottom) during the 1998 growing season, expressed as daily mean (air temperature, O<sub>3</sub> concentration), daily minimum (air temperature, VPD) and daily maximum (air temperature, VPD, PAR).

Figure 4.3 Time course of the climate and  $\text{O}_3$  concentration at the sites Trier-City (top), Trier-University (middle) and Deuselbach (bottom) during the 1999 growing season, expressed as daily mean (air temperature,  $\text{O}_3$  concentration), daily minimum (air temperature, VPD) and daily maximum (air temperature, VPD, PAR).

Figure 4.4 Time course of the climate and O<sub>3</sub> concentration at the sites Trier-City (top), Trier-University (middle) and Deuselbach (bottom) during the 2000 growing season, expressed as daily mean (air temperature, O<sub>3</sub> concentration), daily minimum (air temperature, VPD) and daily maximum (air temperature, VPD, PAR).

Figure 4.5 Time course of the climate and O<sub>3</sub> concentration at the sites Trier-City (top), Trier-University (middle) and Deuselbach (bottom) during the 2001 growing season, expressed as daily mean (air temperature, O<sub>3</sub> concentration), daily minimum (air temperature, VPD) and daily maximum (air temperature, VPD, PAR).

## 4.2 Spatial differences in physical and pollution climate

The results of the spatial analysis of the recorded climate and - to a lesser extent - pollution data basically reflect the geographical location of the three field sites, i.e. the altitude gradient between Trier-City (129 m a.s.l.), Trier-University (255 m a.s.l.) and Deuselbach (480 m a.s.l.) largely determines the site-to site climatic differences.

For all five GPs, the air temperature at the site Trier-City was always higher than at the site Trier-University, while it was always lowest in Deuselbach (only exception: GP 4 in 1998), the site with the highest altitude. However, the differences in mean air temperature between Deuselbach and Trier-University and Trier-University and Trier-City never exceeded 2 °C, in any year (Figure 4.6, Appendix A).

Due to its high dependence on air temperature, the VPD also tended to follow the ranking Trier-City > Trier-University > Deuselbach, with the highest values having been recorded in Trier-City (Figure 4.6, Appendix A). Some exceptions to this observation can however be found towards the end of the growing season of the years 1998 to 2001, when the average VPD value of Deuselbach is often slightly higher than that for the site Trier-University. The very high standard deviations indicate the high variability of the VPD data (Figure 4.6, Appendix A).

Similar magnitudes of variance can be found for PAR, indicating the large scatter of this parameter (Figure 4.6, Appendix A). There is however a general trend for the highest and lowest PAR values having been measured in Deuselbach and Trier-City, respectively, with the PAR values from the Trier-University site usually lying in between this range (Figure 4.6, Appendix A). Most exceptions from these results can be found in 1997, when the lowest PAR values were mostly recorded at the Trier-University site (Appendix A). This divergence from the general trend might be related to an inexact calibration of the measuring device at this site.

The lowest wind speed was always measured at the Trier-University site, closely followed by the measurements of the Trier-City site. In contrast, by far the highest wind speed – at least twice as high as that at the Trier-City site - was always recorded in Deuselbach (Figure 4.6, Appendix A). This ranking is likely to reflect the general wind accessibility conditions of the climate stations (for instance, Deuselbach is a very exposed site without any major vegetation in its vicinity).

The O<sub>3</sub> concentration data also showed a very distinct ranking with the highest and lowest concentrations always found in Deuselbach and Trier-City, respectively. The Trier-University site again represents intermediate conditions (Figure 4.6, Appendix A). These results clearly support the typical O<sub>3</sub> concentration pattern associated with distance from urban (pollution source) areas that are characteristic of this secondary pollutant and driven by the formation of O<sub>3</sub> downwind of precursor pollutant source, i.e. relatively low average (daily, weekly and monthly) O<sub>3</sub> concentrations in urban areas, followed by slightly higher O<sub>3</sub> concentrations in suburban areas and by far the highest concentrations in rural areas.

This distinct urban to rural gradient in O<sub>3</sub> concentration is also reflected in Figure 4.7, which shows the AOT40 values for all GPs of all growing seasons. Especially the bottom right figure clearly shows the much higher O<sub>3</sub> concentrations in Deuselbach. In fact, for most years the AOT40 for Deuselbach is higher than for the combined AOT40 of the two other sites.

### **4.3 Year-to-year variation of physical and pollution climate**

Figure 4.6 gives an overview of the year-to-year differences of the measured air temperature, VPD, PAR, wind speed and O<sub>3</sub> concentration at all three sites by showing the growing season mean of these parameters. In general it appears that when averaged over the entire growing season, the differences of the measured data between the years become marginal.

However, the years 1997 and 1999 were on average warmer and drier than the years 1998, 2000 and 2001 at all sites, with particularly warm and dry periods in August 1997 (Figure 4.1, Appendix A) as well as in July and August 1999 (Figure 4.3, Appendix A). This finding is also reflected by higher average PAR values for 1997 and 1999 (Figure 4.6). In contrast, wind speed was lowest in 1997, especially during the warm and dry months July and August (Appendix A), and highest in year 1998 (Figure 4.6).

The year 2000 experienced the lowest mean O<sub>3</sub> concentrations at all sites, while the highest were recorded in 1997, except for Trier-City, where the highest average O<sub>3</sub>

concentrations were measured in 2001. This trend is enhanced with AOT40 values (Figure 4.7), indicating the frequency of hourly  $O_3$  concentrations that exceeded 40 ppb during the 1997 growing season. The year-to-year differences in  $O_3$  concentration are in general more variable at the site Deuselbach compared to the other two sites.

Figure 4.6 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and  $O_3$  concentration (e) of the growing seasons (5 GPs = 140 days) 1997 until 2001 at the sites Trier-City, Trier-University and Deuselbach. Wind speed data at the site Trier-University were not available for 1997.

#### 4. Climate of growing seasons 1997 to 2001 in the Trier region

Figure 4.7 Calculated AOT40 values for growing periods 1 to 5 (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach for the study years 1997 until 2001. The bottom right figure represents the AOT40 of the entire growing season (i.e. sum of AOT40 of GP 1 to 5) at all three sites for all five study years.

## 5 Description and analysis of model input data

In this chapter, observed  $g_s$ -data of both white clover clones recorded during the summer months of the years 1997 until 2001 and the co-occurring meteorological parameters are described and statistically analysed. Since ANNs are known for their limited ability to extrapolate outside the range of input data, it is extremely important in this study to ensure that the input dataset is truly representative of the entire range of meteorological conditions of a typical West European growing season in order to be able to develop a model that is capable of predicting  $O_3$  fluxes for these conditions.

### 5.1 Descriptive statistics of model input data

The statistical interpretation of the observed  $g_s$  values for each of the two clones is described in relation to the meteorological parameters and  $O_3$  concentrations in Table 5.1. In addition, statistics for two  $O_3$  exposure indices and the exposure time are given. The NC-S and NC-R datasets comprise in total 9113 readings representing 23 days and 5224 readings representing 13 days, respectively. For the development of a combined  $g_s$  model, these two datasets were merged.

Both datasets comprise a similar range of PAR-data representing conditions of total darkness ( $PAR = 0 \mu\text{mol m}^{-2} \text{s}^{-1}$ ) up to light saturation ( $PAR$  of approx. 1200 up to 2100  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) with an average PAR value for both datasets of approx. 1100  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . The average VPD value of 1.2 kPa is identical for both datasets as well as the minimum value of 0.1 kPa, but the amplitude of the VPD data is higher for the NC-R dataset due to its higher maximum value of VPD at 3.4 kPa as compared to a VPD of 2.9 kPa for the NC-S dataset. Analysis of the air temperature shows a very similar pattern with an identical mean and similar first and third quartile values, but a greater range of the temperature data for the NC-R dataset from 12.1 °C to 34.4 °C (amplitude: 22.3 °C) as compared to the NC-S dataset from 14.3 °C to 31.5 °C (amplitude: 17.2 °C). This indicates a higher number of outliers within the NC-R dataset in spite of the data quality control process.

## 5. Description and analysis of model input data

Table 5.1 Descriptive statistics analysing  $g_s$ -, meteorological and  $O_3$  concentration data recorded during the years 1997 until 2001 at the Trier-University site and corresponding exposure indices estimated for particular exposure periods. All parameters function as input for the ANN-model apart from  $g_s$ , which is the model output parameter (NC-S:  $n = 9113$ ; NC-R:  $n = 5224$ ).

There is little difference between the mean O<sub>3</sub> concentrations of 48.3 ppb and 47.1 ppb measured for the NC-S and the NC-R dataset respectively, and the range in concentration values is also similar at 9.3 ppb to 85.5 ppb and 10.0 ppb to 83.1 ppb for the NC-S and the NC-R datasets respectively. It can therefore be assumed that the datasets are representative of the range of meteorological and O<sub>3</sub> concentration conditions that would be typical during the growing season of grasslands and crops in the Trier region. Any data that might fall outside of these typical conditions are discussed below.

The mean of the exposure time (in days) representing the age of the test plants at the time of gas exchange measurements differ between 75 and 85 days for the sensitive and resistant clone respectively, indicating that the g<sub>s</sub> measurements for the NC-R clone were taken on plants that had on average been exposed to ambient air for 10 days longer than their sensitive counter-parts. However, this difference is marginalized by the fact that the median value of the exposure time only slightly differs (i.e. by one day), as do the first and third quartiles.

A statistical analysis was also carried out for the calculated exposure indices “AOT40 since exposure”, which represents the accumulated exposure at the time of each gas exchange measurement (i.e. O<sub>3</sub> concentrations above 40 ppb) the plant had been exposed to since its transfer to the ambient air field site, and “AOT40 of last 12 days”, representing the accumulated exposure of the last 12 days. This is the average exposure time of the white clover cultivar prior to the incidence of the first visible foliar injury symptoms. No major differences were found in the “AOT40 since exposure” index between the datasets of the two clones, whereas the “AOT40 of last 12 days” index differed significantly between both datasets: the average value of the NC-S clone was more than two times higher than that of the NC-R clone, indicating that the g<sub>s</sub> measurements were on average carried out on NC-S plants that had recently been exposed to more than double the AOT40 dose than NC-R plants.

## 5.2 Distribution of input data

The distribution of the  $g_s$ -data collected for both clones is further detailed in Figure 5.1 and Table 5.2. The high representation of more than 53 % of  $g_s$  values below 300  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  PLA (projected leaf area) for the NC-R clone is noticeable, whereas only 30% of the NC-S  $g_s$ -data fall into this range.

Figure 5.1 Distribution of  $g_s$ -data for the NC-S (left) and NC-R (right) clone.

Table 5.2 Absolute and relative distribution of  $g_s$ -data of both clover clones.

$g_s$ [ $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ]	NC-S	NC-S %	NC-R	NC-R %
0.00 - 100.00	379	4.2	542	10.4
100.01 - 200.00	1093	12.0	679	13.0
200.01 - 300.00	1318	14.5	1574	30.1
300.01 - 400.00	2194	24.1	1245	23.8
400.01 - 500.00	1799	19.7	575	11.0
500.01 - 600.00	1462	16.0	418	8.0
600.01 - 700.00	666	7.3	183	3.5
700.01 - 800.00	197	2.2	7	0.1
800.01 - 900.00	5	0.1	1	0.0

The distribution of the  $g_s$  datasets of both clones is shown in Table 5.3 in relation to selected classes of key meteorological parameters,  $\text{O}_3$  concentrations, time and  $\text{O}_3$  exposure indices. Note that the parameters “Year”, “Month” and “Time of day” are only shown for analysis purposes and have not been included as inputs in the ANN models. This is because it is assumed the information given by the latter two is accounted for by the variation in the meteorological input parameters over the course of the growing season, whereas the parameter “Year” is not considered as being important given the type of model being developed.

Table 5.3 Relative distribution of g<sub>s</sub>-datasets of both clover clones according to key meteorological parameters, O<sub>3</sub> concentration and time.

7500-8000	0.0	0.0			
8000-8500	8.0	12.7			

Table 5.3 clearly demonstrates that the input data of both clones are in general well distributed over a broad range, especially for the important meteorological input parameters air temperature, VPD and PAR. However, the frequency of data in different classes for the parameters “exposure time” (e.g. class “100-120 days” for NC-S), “AOT40 since exposure” and “AOT40 of last 12 days” show a higher variability, in particular for the NC-R dataset.

This variability is obvious in the scatter plots shown in Figure 5.2 and 5.4. In general, the data cloud is slightly denser and less patchy for the NC-S dataset, which can partly be explained by the higher number of data points of this dataset in comparison with the NC-R dataset. In addition, these scatter plots indicate that the parameters “ozone”, “exposure time”, “AOT40 since exposure” and “AOT40 of last 12 days” are available in hourly time steps, whereas the meteorological parameters had been recorded every minute.

## 5. Description and analysis of model input data

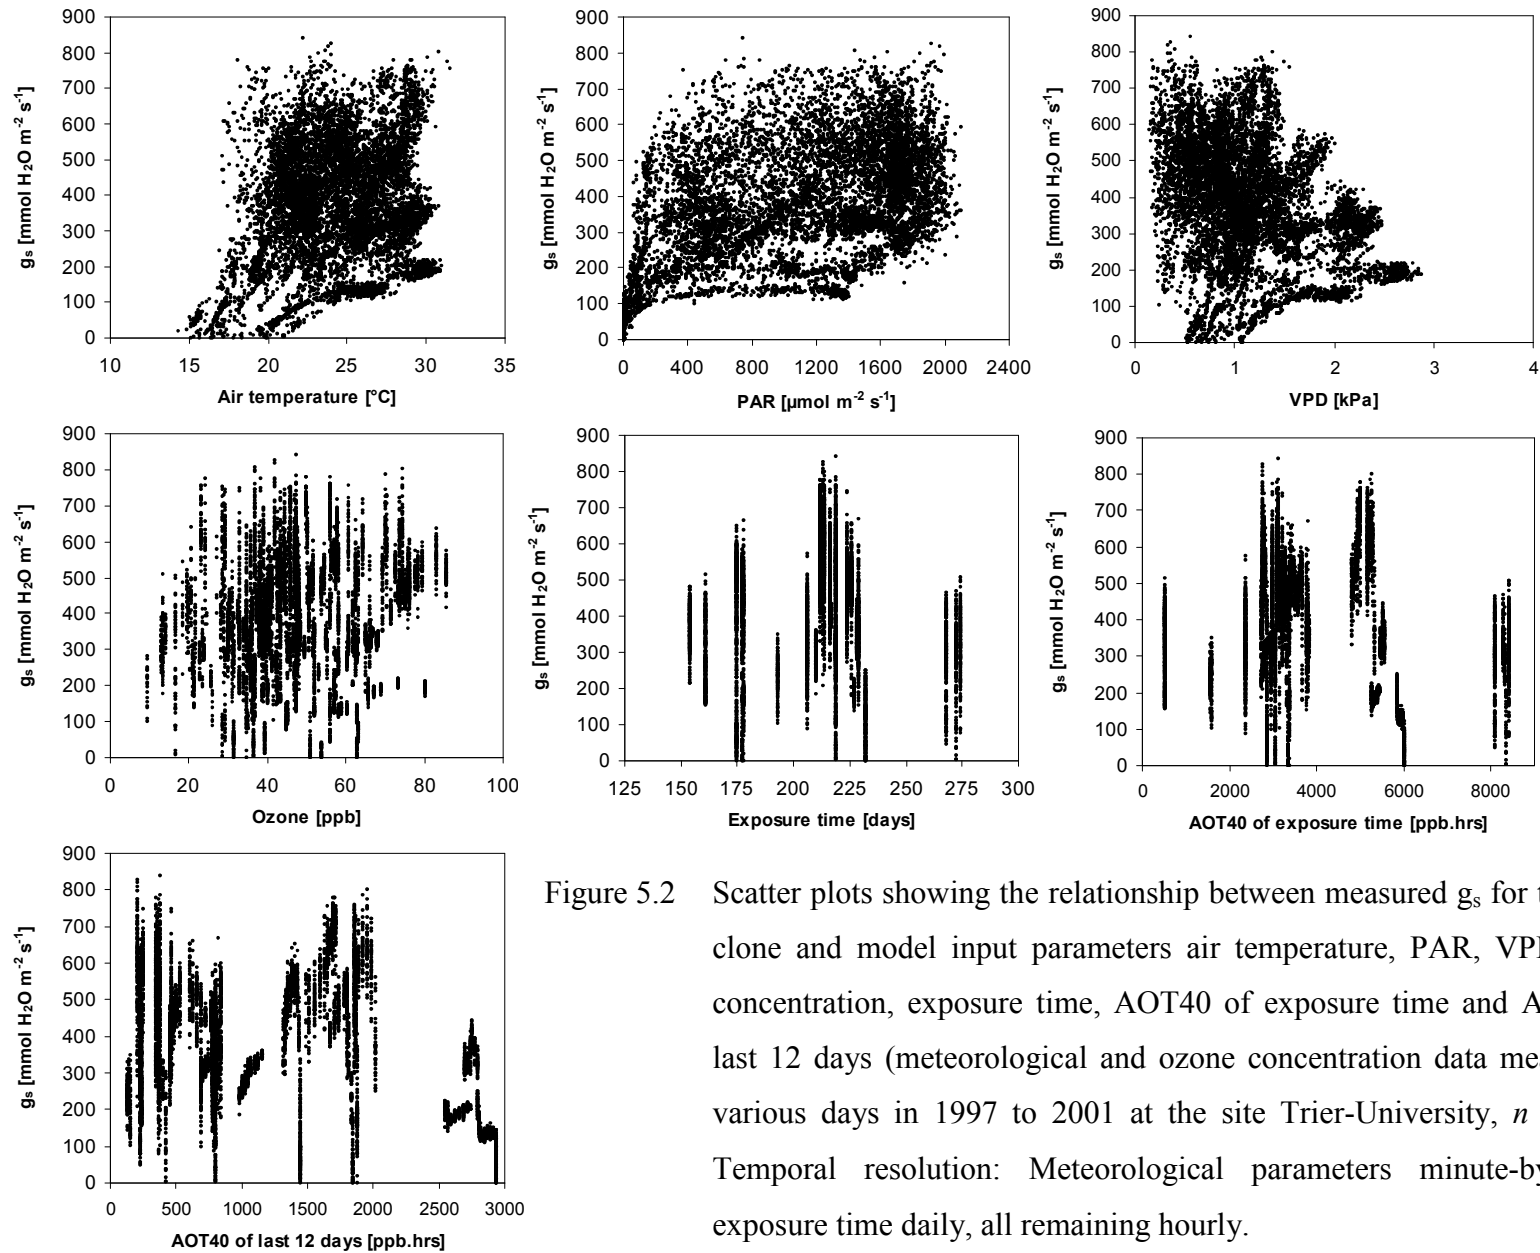

Figure 5.2 Scatter plots showing the relationship between measured  $g_s$  for the NC-S clone and model input parameters air temperature, PAR, VPD, ozone concentration, exposure time, AOT40 of exposure time and AOT40 of last 12 days (meteorological and ozone concentration data measured at various days in 1997 to 2001 at the site Trier-University,  $n = 9113$ ). Temporal resolution: Meteorological parameters minute-by-minute, exposure time daily, all remaining hourly.

## 5. Description and analysis of model input data

Figure 5.3 Scatter plots showing the relationship between meteorological parameters VPD, air temperature and PAR, as well as between  $\text{O}_3$  concentration and these meteorological parameters of the NC-S dataset (measured data from various days in 1997 to 2001 at the site Trier-University,  $n = 9113$ ). Temporal resolution: Meteorological parameters minute-by-minute,  $\text{O}_3$  concentration hourly.

## 5. Description and analysis of model input data

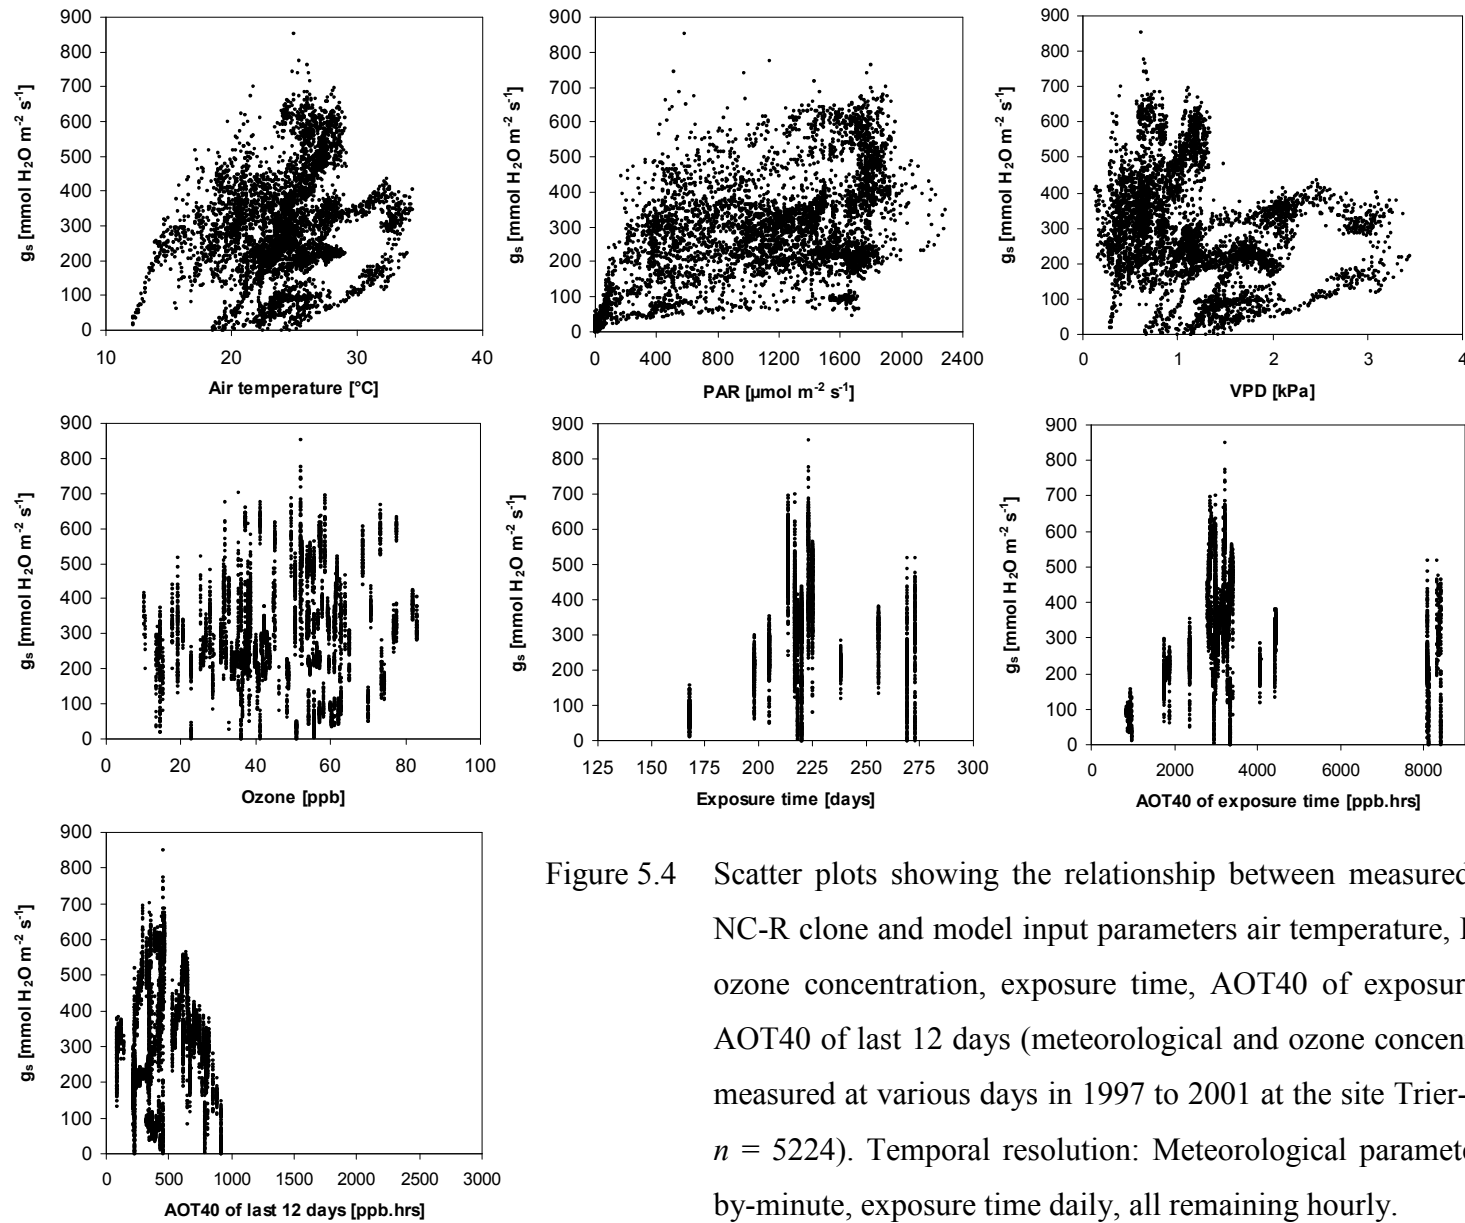

Figure 5.4 Scatter plots showing the relationship between measured  $g_s$  for the NC-R clone and model input parameters air temperature, PAR, VPD, ozone concentration, exposure time, AOT40 of exposure time and AOT40 of last 12 days (meteorological and ozone concentration data measured at various days in 1997 to 2001 at the site Trier-University,  $n = 5224$ ). Temporal resolution: Meteorological parameters minute-by-minute, exposure time daily, all remaining hourly.

## 5. Description and analysis of model input data

Figure 5.5 Scatter plots showing the relationship between meteorological parameters VPD, air temperature and PAR, as well as between  $\text{O}_3$  concentration and these meteorological parameters of the NC-R dataset (measured data from various days in 1997 to 2001 at the site Trier-University,  $n = 9113$ ). Temporal resolution: Meteorological parameters minute-by-minute,  $\text{O}_3$  concentration hourly.

A first indication of the relationship between the parameters air temperature and PAR, VPD and O<sub>3</sub> concentration, between PAR and VPD and O<sub>3</sub> concentration as well as between VPD and O<sub>3</sub> concentration is given in Figure 5.3 and 5.5 for the NC-S and NC-R dataset, respectively. The scatter plots look rather similar for both datasets, with again a slightly higher patchiness for the NC-R dataset. Most evident is the strong dependency of VPD on air temperature (positive relationship), but also O<sub>3</sub> concentration shows a distinct positive correlation with air temperature. Similarly, the O<sub>3</sub> concentration is also positively correlated with VPD. The relationship between VPD as well as air temperature with PAR is slightly less obvious, though there is no doubt that both parameters are positively correlated with PAR. Only the correlation between O<sub>3</sub> and PAR is hard to define from the scatter plots of the present datasets.

These findings are also supported by the results of the Spearman's rank-order correlation test shown in Tables 5.4 and 5.5. It revealed, for both datasets, a significant positive association between air temperature and VPD with  $r = 0.70$  and  $r = 0.74$  for the NC-S and NC-R dataset, respectively. A similarly strong significant correlation was found between air temperature and O<sub>3</sub> concentration with correlation coefficients of  $r = 0.68$  and  $r = 0.76$  for the NC-S and NC-R dataset, respectively. This clearly indicates the strong dependence of tropospheric O<sub>3</sub> formation on air temperature, which can for instance often be experienced during hot summer periods in Germany.

Surprisingly, the association between air temperature and PAR is less strong, though also highly significant (it has to be pointed out that due to the large sample size, most correlations have been found to be highly significant).

Furthermore, there is a significant positive association between  $g_s$  and air temperature and PAR, whereas the correlation between  $g_s$  and VPD is significantly negative. The low correlation coefficients and contradictory (i.e. negative for NC-S but positive for NC-R dataset) associations between  $g_s$  and O<sub>3</sub> concentration, exposure time, "AOT40 of exposure" and "AOT40 of last 12 days" indicate the limited suitability of these parameters for predicting  $g_s$ .

Table 5.4 Results of the Spearman's rank-order correlation for NC-S clone dataset including  $g_s$  [ $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ] and all 7 input variables used for the ANN  $g_s$  model, i.e. air temperature [ $^{\circ}\text{C}$ ], VPD [kPa], PAR [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ],  $\text{O}_3$  concentration [ppb], exposure time [days], "AOT40 of exposure time" [ppb.hrs] and "AOT40 of last 12 days" [ppb.hrs].

### 5.3 Comparison of NC-S and NC-R stomatal conductance data

An important feature of this study was whether or not it would be necessary and desirable to develop separate ANN-based flux models for the NC-S and NC-R clover clones. This was assessed on the basis of results describing the statistical differences in  $g_s$  of both clones. In order to check the hypothesis that the mean  $g_s$  of both clover clones did not differ significantly, a statistical test of difference was carried out.

Due to the results of the Kolmogorov-Smirnov test (K-S test) for normal distribution, which confirmed that the distribution of both datasets differed significantly from normal ( $P = 0.000$  for both datasets, see also Figure 5.6), the nonparametric Mann-Whitney U-test was used to test the statistical difference and revealed that the hypothesis that both  $g_s$  datasets are not significantly different from each other had to be rejected ( $P = 0.000$ ). This result is supported by the box-plots presented in Figure 5.7, which show that the median values for  $g_s$  of the NC-S and the NC-R clone are 375.6 and 288.2, respectively (cf. Table 5.1). However, note that the absolute  $g_{\max}$  is almost identical for both clones: NC-S = 841.1 mmol H<sub>2</sub>O m<sup>-2</sup> s<sup>-1</sup>, NC-R = 852.2 mmol H<sub>2</sub>O m<sup>-2</sup> s<sup>-1</sup> (cf. Table 5.1).

Figure 5.6 Histogram showing the distribution of the  $g_s$  datasets of the NC-S (left) and NC-R (right) clover clone (NC-S,  $n = 9113$ ; NC-R,  $n = 5224$ ).

Figure 5.7 Box-plots showing the distribution of  $g_s$ -measurements of the NC-S (left) and NC-R (right) clover clone (NC-S,  $n = 9113$ ; NC-R,  $n = 5224$ ). Note the outliers for the NC-R clone.

To avoid any possible bias that may be introduced by the climatic conditions during the experimental campaign, i.e. that particular climatic conditions may be more favourable when measuring gas exchange of the NC-S plants leading to a higher  $g_s$ , it was decided to create a subset of both  $g_s$  datasets representing non-limiting meteorological conditions for white clover. Hence, these sub-datasets consist of measurements carried out for the following meteorological conditions considered to be optimum for  $g_s$ : air temperature between 22.5 and 25.0 °C, VPD between 0.75 and 1.25 kPa and PAR between 1200 and 1600  $\mu\text{mol m}^{-2} \text{s}^{-1}$  (light saturation).

The derived  $g_s$ -subsets of data (NC-S:  $n = 186$ ; NC-R:  $n = 197$ ) were tested for normal distribution (significantly different from normal distribution with  $P = 0.43$  and  $P = 0.05$  for NC-S and NC-R clone, respectively; also see Figure 5.8) and statistical difference from each other using the Mann-Whitney U-test, which revealed – similar to the test carried out for the entire dataset – a significantly higher  $g_s$  for the NC-S as compared to the NC-R clone ( $P = 0.00$ ). This result is again supported by the box-plots presented in Figure 5.9, which show that the median  $g_s$  of the NC-S and the NC-R clone is 464.45 and 254.60, respectively. It is obvious that here the difference

between the median  $g_s$  of both clones is even larger than found for the comparison of the entire datasets (see above).

These results showed that it was necessary to develop separate models for the NC-S and NC-R clones used in this study.

Figure 5.8 Histogram of distribution of  $g_s$ -data of the NC-S (left) and NC-R (right) clover clone measured under non-limiting meteorological conditions for  $g_s$  (NC-S,  $n = 186$ ; NC-R,  $n = 197$ ).

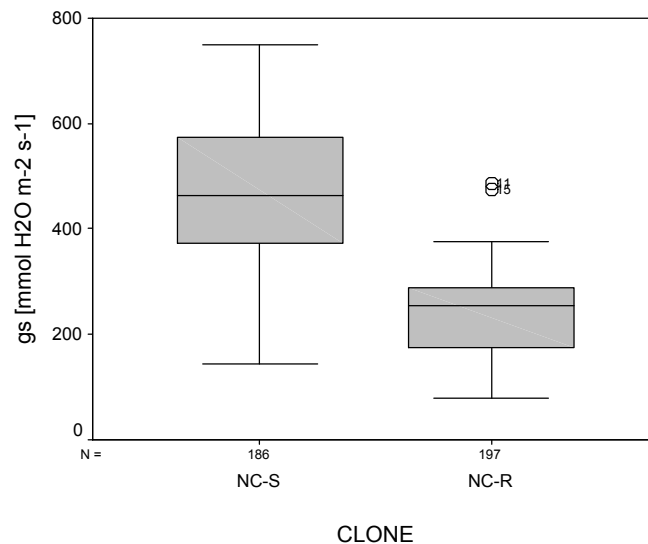

Figure 5.9 Box-plots showing the distribution of  $g_s$ -measurements of the NC-S (left) and NC-R (right) clover clone measured under non-limiting meteorological conditions for  $g_s$  (NC-S,  $n = 186$ ; NC-R,  $n = 197$ ).

#### 5.4 Regression analysis of input data

Prior to the development of the ANN-based flux models for both clover clones, a stepwise (multiple) regression analysis of both  $g_s$  datasets was carried out to gain a first impression of the suitability of the seven input parameters in explaining the variation in the observations of the output parameter  $g_s$ . The results of this analysis are given in Table 5.6 and Table 5.7 for the NC-S and NC-R clover clone, respectively.

When all seven input parameters, i.e. air temperature [ $^{\circ}\text{C}$ ], VPD [kPa], PAR [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ],  $\text{O}_3$  concentration [ppb], exposure time [days], “AOT40 of exposure time” [ppb.hrs] and “AOT40 of last 12 days” [ppb.hrs] are included as independent variables in the regression analysis (Model 7 in Tables 5.6 and 5.7), they are able to explain 62.8 % and 55.3 % of the variation in  $g_s$  of the NC-S and NC-R clover clone, respectively. Investigation of the component parts of the regression analysis suggests that for both datasets, PAR, VPD and air temperature - in that particular order - contributed the most to the explanation of the variation in  $g_s$ , i.e. 53.5 % and 48.4 % for the NC-S and NC-R dataset, respectively. The stepwise addition of the remaining four input parameters only slightly increased the regression coefficients and was not in the same order of importance for the NC-S and NC-R datasets (Tables 5.6 and 5.7).

Despite the fact that the multiple linear regression assumes not only a total independence of all independent variables but also a direct, combined linear effect of all independent variables on the dependent variable, it is very often used for describing complex biological cause-effect relationships like the one addressed in this study. Since both these assumptions are not valid for the two model input datasets used in this study (see for example results of the Spearman’s rank-order correlation in Chapter 5.2.1), a multiple regression analysis seems to be less suitable for predicting  $g_s$  with the help of physical and pollution climate data using the NC-S and NC-R datasets available in this study.

It is expected that ANNs will perform better since they are capable of allowing for the highly complex, non-linear relationship between  $g_s$  and the prevailing physical- as well as pollution-climate conditions.

## 6 Development of the stomatal conductance models

### 6.1 General development of ANN-based stomatal conductance models

#### 6.1.1 Architecture of network used in this thesis

Figure 6.1 shows the architecture of the backpropagation neural network used in this thesis when using all available input variables. Neurons from one layer feed-forward to all neurons of the next layer. There are no lateral connections within layers nor any feed-back connections between layers (feed-back connections are characteristic for recurrent ANNs used for time series modelling (cf. Pineda, 1987)).

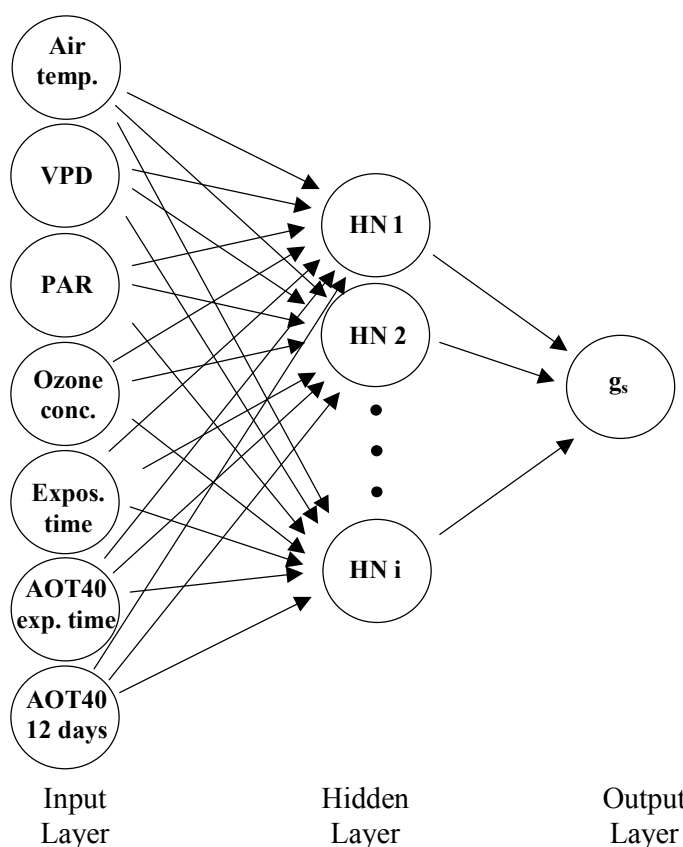

Figure 6.1 Architecture of the neural network used in this thesis, with air temperature [ $^{\circ}\text{C}$ ], VPD [ $\text{kPa}$ ], PAR [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ],  $\text{O}_3$  concentration [ $\text{ppb}$ ], exposure time [ $\text{days}$ ], AOT40 of exposure time [ $\text{ppb.hrs}$ ] and AOT40 of last 12 days [ $\text{ppb.hrs}$ ] as input and  $g_s$  [ $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ] as output.

The input layer of the main initial ANN comprised seven neurons representing seven elements of information (variables) at the entry of the network: air temperature [ $^{\circ}\text{C}$ ], VPD [kPa], PAR [ $\mu\text{mol m}^{-2} \text{s}^{-1}$ ],  $\text{O}_3$  concentration [ppb], exposure time [days], AOT40 of exposure time [ppb.hrs] and AOT40 of last 12 days [ppb.hrs]. These elements of information are equivalent to independent variables in multiple regression analysis. The output layer of all neural networks (main and sub-networks) developed within this thesis consists of one neuron representing the stomatal conductance to water vapour ( $g_s$ ) [ $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ].

### **6.1.2 Data import and scaling**

Typically for ANNs, the values of input and output neurons – here imported as Excel-spreadsheets by NeuroShell 2 - are scaled to the numeric range of 0 to 1 to ensure an identical range for all involved model variables which compensates effects of outliers in the dataset. Once the training is completed, the output values are re-scaled by reversing the action (e.g. Dimopoulos et al., 1999). NeuroShell 2 performs these two steps automatically, using a linear scaling function by default.

### **6.1.3 Division of input dataset into training, test and validation dataset**

In order to prevent over-training of the network and to improve the generalisation and prediction ability of the final network, the two initial datasets of this thesis (i.e. measured  $g_s$  data for NC-S and NC-R clover clones with corresponding  $\text{O}_3$  concentrations and meteorological variables) were randomly divided into a training, test and validation dataset in the relation of 60:20:20 using the NeuroShell 2 extraction command.

Prior to the main network training, this procedure was – as a pilot test - repeated three times which resulted in three different dataset divisions per clover clone dataset. The reason for this pilot test was to analyse whether or not different training, test and validation datasets (different in terms of the random selection rather number of data points, i.e.  $n$  and the relation 60:20:20 were always kept constant) might lead to different model results. This procedure was carried out for both the NC-R ( $n = 5224$ ) and NC-S ( $n = 9113$ ) dataset using all seven input parameters with 20 and 25 hidden

neurons (dataset size-related hidden neuron numbers suggested by NeuroShell 2), respectively. The variation of momentum and learning rate according to the ranges and steps described below led to 48 different sub-models for each dataset division. These sub-models were then applied to the previously extracted validation dataset with a subsequent comparison of predicted and measured  $g_s$ .

Table 6.1 shows the average predictive performance (expressed as coefficient of multiple determination ( $R^2$ ) of predicted vs. measured values) for all three dataset divisions of both  $g_s$ -datasets (indicated as dataset 1 – 3 in Table 6.1). A varying random extraction of 60 % of the input data for training purposes of the model did result in slightly different predictive performances of the  $g_s$  model. However, the average  $R^2$  - values differed to such a marginal extent that it was considered justifiable to stick to just **one** separation process of input data into training, test and validation data in the following training phase of the  $g_s$  models.

Table 6.1 Test of different separation of NC-S and NC-R datasets into training, test and validation datasets on predictive performance of models, expressed as average ( $n = 48$  sub-models)  $R^2$  value of predicted vs. measured  $g_s$ . Each dataset represents a different random division of input data into 60 % training, 20 % test and 20 % validation data (NC-S:  $n = 9113$ ; NC-R:  $n = 5224$ ).

	NC-S			NC-R		
	Dataset 1	Dataset 2	Dataset 3	Dataset 1	Dataset 2	Dataset 3
Mean of $R^2$	0.869	0.862	0.877	0.899	0.895	0.893
Stdev. ( $\sigma$ )	0.053	0.056	0.045	0.013	0.013	0.014

#### 6.1.4 Structure of hidden layer

The number of neurons in the hidden layer was varied throughout the training phase of the neural networks. For the identification of the initial number of hidden neurons, NeuroShell 2 offers the computation of a default number according to the following formula:

$$\text{Number of hidden neurons} = 0.5 * (\text{number of Inputs} + \text{Output}) + \text{Square Root of} \\ \text{number of patterns in training dataset} \quad (6.1)$$

This led to an initial number of hidden neurons of 20 and 25 for the NC-R and NC-S dataset, respectively. These were considered the maximum numbers of hidden neurons and were subsequently reduced in steps of 1 down to 3 in order to find the minimum number of hidden neurons that could still reveal and hence predict the complex relationship between inputs and the output. The most commonly used method to identify the optimal number of hidden neurons ensuring the best prediction ability of the network is trial and error, which was as well used in this thesis. A further reason for varying the number of hidden neurons was the differing amount of input variables of sub-networks of the main network. These sub-networks were trained to test the importance of each variable for the predictive power of the network (see below). In other words, the performance of various sub-networks with different combinations of input variables were compared with the performance of the main network including all seven input variables.

A unique tool of NeuroShell 2 is the possibility to divide the hidden layer in three different slabs, i.e. groups of hidden neurons (not to be confused with multiple hidden layers working in serial rather than in parallel). This procedure provides the opportunity to select different activation functions for different slabs, so that the output layer will get “different views” of the data. In other words, different activation functions detect different features in a pattern processed through a network. For instance, one activation function applied to one slab might detect features in the mid-range, while a second slab with a different activation function may detect features from the upper or lower end of the dataset (Ward System Group Inc., 1996). In practice, this means that the total amount of hidden neurons is divided by three with each cluster of hidden neurons then being equipped with a different activation function.

Prior to the model development, the prediction ability of networks trained with this three-slab tool using different combinations of activation functions such as sigmoid logistic, hyperbolic tangent, Gaussian and/or Gaussian complement was compared with the predictive ability of a classic three-layer network. It was found that the three-

slab networks with a combination of the following three activation functions, where  $f(a_j)$  is the activation function of the  $j^{\text{th}}$  neuron, always outperformed not only the classic three-layer network, but also three-slab networks with other combinations of activation functions:

i) Gaussian:

$$f(a_j) = \exp(-a_j^2) \quad (6.2)$$

ii) Gaussian complement:

$$f(a_j) = 1 - \exp(-a_j^2) \quad (6.3)$$

and

iii) hyperbolic tangent (tanh):

$$f(a_j) = \tanh(a_j^2) \quad (6.4)$$

In contrast, a non-linear sigmoidal (sigmoid logistic) activation function was used to calculate the output ( $g_s$ ) based on the weighted and subsequently summed input signals coming from the hidden layer:

$$f(a_j) = \frac{1}{1 + \exp^{-a_j}} \quad (6.5)$$

where  $f(a_j)$  is the activation function of the  $j^{\text{th}}$  neuron.

### 6.1.5 Setting of momentum and learning rate

The optimum configuration of the main model in terms of the settings of the learning rate and momentum – i.e. range and incremental steps – was identified via various tests prior to the main training phase of the networks. It appeared that for securing the best possible network training with the given noise in the input datasets, a range from 0.05 to 0.5 and 0.05 to 0.7 was most suitable for learning rate and momentum, respectively. The possible combinations (and incremental steps) of these weighting parameters are listed in Table 6.2. Accordingly, these 48 weighting parameter combinations were always applied during each training epoch (where an epoch represents one complete pass through the network without changing the number of

hidden neurons) resulting in 48 sub-models for model runs, with for example 25, 24, 23 etc. hidden neurons. As an example, this procedure resulted for the NC-S dataset using all seven input parameters in 1104 sub-models (48 model runs each for models with 25, 24, 23.... down to 3 hidden neurons  $\rightarrow$  48 (weighting parameter combinations)  $\times$  23 (hidden neuron classes) = 1104 (sub-models)). From these 1104 sub-models, the one with the best predicting ability of  $g_s$  was chosen as the final model for that particular combination of input parameters.

Table 6.2 Combinations of learning rate ( $\eta$ ) and momentum ( $\mu$ ) used during training of ANNs.

$\mu \backslash \eta$	0.05	0.1	0.2	0.3	0.4	0.5
0.05	✓	✓	✓	✓	✓	✓
0.1	✓	✓	✓	✓	✓	✓
0.2	✓	✓	✓	✓	✓	✓
0.3	✓	✓	✓	✓	✓	✓
0.4	✓	✓	✓	✓	✓	✓
0.5	✓	✓	✓	✓	✓	✓
0.6	✓	✓	✓	✓	✓	✓
0.7	✓	✓	✓	✓	✓	✓

### 6.1.6 Stopping criteria for network training

The training was stopped when the sum of squared errors between the predicted output value of the training and the output values of the test set was at its minimum (precisely, when the number of events – i.e. the presentation of a single training pattern to the network - since the internally calculated minimum last changed, exceeded 20,000) or the learning epochs reached a total number of 400. The resulting network was then applied to the validation dataset to test its general accuracy in predicting  $g_s$ .

## 6.2 General evaluation of models

### 6.2.1 *Criteria for assessing predictive performance of models*

The coefficient of determination ( $R^2$ ) and the mean squared error (MSE) of the relationship between modelled and observed  $g_s$  were considered the main indicators for assessing the predictive performance of all models and sub-models. The higher the  $R^2$  and the lower the MSE, the better the model. However, throughout the thesis in all tables and figures only the  $R^2$  will be stated as the main indication for the performance of a network/model.

### 6.2.2 *Sensitivity analysis*

Furthermore, in order to evaluate this first judgement based on  $R^2$  and MSE, as well as to test the performance of these models in terms of their predictive power over the entire range of all involved input parameters, a sensitivity analysis was carried out for each sub-model. This analysis gives a good visual indication of the relative importance of single variables on the dependent variable ( $g_s$ ). This analysis involved the creation of effect-curves showing the dependence of  $g_s$  on each independent variable by varying the value of one independent parameter in constant steps across its entire range while keeping the value of all other independent variables constant at their mean.

Figure 6.2 gives an example for a sensitivity analysis carried out for two different sub-models for the NC-S dataset. These sub-models only varied in their learning rate and momentum (i.e. the number of inputs and hidden neurons was identical), but show different predictive performances: The relationship between  $g_s$  and PAR is less clear (small range of  $g_s$ , high  $g_s$  value for PAR = 0  $\mu\text{mol m}^{-2} \text{s}^{-1}$ ) for the sub-model with a learning rate of 0.3 and a momentum of 0.7 (graph g in figure 6.2) than for the sub-model with a learning rate of 0.2 and a momentum of 0.1 (graph c). Furthermore, the former shows an unexpected slight increase of  $g_s$  as VPD increases from 0 to 0.5 kPa (graph f), as well as a less clear influence of the exposure time on  $g_s$  (graph h).

In this case, the sub-model with a learning rate of 0.2 and a momentum of 0.1 (graphs a to d) would be considered the better choice due to its superior ability to predict  $g_s$  as a function of various meteorological parameters and time.

Figure 6.2 Sensitivity analysis of two NC-S  $g_s$  sub-models with identical number of inputs ( $n = 7$ ) and hidden neurons ( $n = 9$ ), but differing learning rates and momentums (0.2 and 0.1 (a - d) as opposed to 0.3 and 0.7 (e - h)). Shown are relationships between modelled  $g_s$  and the entire range of the parameters air temperature (a, e), VPD (b, f), PAR (c, g) and exposure time (d, h). For each graph, all other six input parameters were kept at their overall mean (black curve) and median (grey curve).

Figure 6.3 Sensitivity analysis of two NC-S  $g_s$  sub-models with identical number of inputs ( $n = 7$ ) and hidden neurons ( $n = 9$ ), but differing learning rates and momentums (0.2 and 0.1 (a - c) as opposed to 0.3 and 0.7 (d - f)). Shown are relationships between modelled  $g_s$  and the entire range of the parameters  $O_3$  concentration (a, d), AOT40 of exposure time (b, e) and AOT40 of last 12 days (c, f). For each graph, all other six input parameters were kept at their overall mean (black curve) and median (grey curve).

A somewhat subjective scoring system was set up for the visual assessment of the performance of the sensitivity analysis, which was applied to all sub-models:

- 1 = good performance ( $g_s$  shows “typical” - i.e. similar to what is reported in text books - dependence on meteorological variables and time);
- 2 = mediocre performance ( $g_s$  shows an unexpected relationship to at least one meteorological variable or time);

3 = bad performance (the relationship between  $g_s$  and a majority of meteorological variables and/or time is inconsistent).

The relationships between  $g_s$  and the  $O_3$  concentration, “AOT40 since exposure” and “AOT40 of last 12 days” showed no clear trend for the same sub-models as described above, as can be seen in Figure 6.3.

### 6.2.3 Diurnal time course test of model performance

In addition, all sub-models were always applied to two different diurnal time courses of observed meteorological data to get a second visual indication of the networks' performance and to identify the ability of the network to cope with time series of data (e.g. from 7 a.m. till 9 p.m.). The two diurnal time courses used for this analysis were selected to represent a cloudless, warm summer day with a perfect parable-shaped PAR curve (Figure 6.4, graphs a and c), and a day with interrupted sunshine periods which resulted in distinct peaks of PAR, temperature and VPD (Figure 6.4, graphs b and d).

In this example, both sub-models predict obvious incremental steps of  $g_s$  (slightly larger for the 0.3/0.7 model, Figure 6.4 graph c) during the late morning hours of the cloudless summer day (graphs a and c), which when compared to the meteorological parameters can only be judged as a model artefact. At least, the 0.2/0.1 model is able to cope with the sudden, albeit brief drop in PAR at 18:20, which is not the case for the other model. For the cloudy day (Figure 6.4, graph b and d), the 0.2/0.1 model clearly reacts to the various drops in PAR when predicting  $g_s$ , i.e.  $g_s$  decreases when PAR decreases and vice versa, which is not the case for the 0.3/0.7 model.

Again, a somewhat subjective scoring system was set up for the visual assessment of the performance of the application of sub-models to diurnal time courses of measured meteorological data:

- 1 = good performance (predicted diurnal time course of  $g_s$  shows good fit with measured diurnal time courses of PAR and air temperature);
- 2 = mediocre performance (some divergence between predicted time course of  $g_s$  and time courses of meteorological parameters);

3 = bad performance (no clear relationship between time course of  $g_s$  and time courses of meteorological parameters and/or clear artefacts in time course of  $g_s$ )

Figure 6.4 Application of two NC-S  $g_s$  sub-models only differing in their learning rate and momentum (0.2 and 0.1 (a, b) as opposed to 0.3 and 0.7 (c, d)) to two diurnal time courses of measured meteorological data. Graph a and c: 08/08/98, graph b and d: 14/08/00. VPD (not shown) showed a very similar time course to air temperature.

It is important to bear in mind that the diurnal time courses used for this analysis consisted of meteorological data (air temperature, VPD and PAR) that were simultaneously measured alongside with  $g_s$ , i.e. these are meteorological data measured with the gas exchange measuring system rather than at the nearby meteorological station. This gave a clearer impression of how the clover clones actually reacted to the prevailing meteorological conditions.

However, since modelled data would generally only be applied to data that are **not** being used for the training of the model, which would have resulted in the exclusion of entire measured diurnal datasets (consisting of approx. 600 single data points) during the model development – a sacrifice thought to be too large here -,  $g_s$  sub-

models for the NC-S clone were always applied to diurnal time courses of meteorological data recorded during the measurements of  $g_s$  on the NC-R clover clone, and *vice versa*. The downside of this approach is that the modelled  $g_s$  data for one clone could only be compared with measured  $g_s$  data of the other clone. Given the significant difference in the average  $g_s$  (cf. Chapter 5.3) between the two clover clones, this comparison was judged to be of limited use for assessing the predictive performance of each developed sub-model. However, while the mean  $g_s$  differed significantly between clones, the general response of the  $g_s$  to PAR, air temperature and VPD was very similar for both clones. In other words the diurnal  $g_s$  profiles would be quite similar and hence could be used to indicate how the white clover responds to the prevailing meteorology over the course of a day.

#### **6.2.4 Assessment of parameter contribution**

In order to better understand the internal functioning of an ANN and to get an idea how to further develop the network - e.g. which input variable could be excluded without losing too much information about the intrinsic, complex relationship between inputs and output -, it is of great help to determine the contribution of each input variable to the network's output.

The two most commonly used approaches for this parameter contribution analysis are the Garson's algorithm and the connection weight approach (cf. Chapter 2.4). Both require two matrices containing input-hidden and hidden-output weights. From these, the contribution of each input neuron to the output via the hidden neurons is calculated as the product of the input-hidden and hidden-output connection. While the Garson's algorithm then calculates the relative contribution of each input neuron to the outgoing signal of each hidden neuron and the sum of contributions of each input neuron to gain the relative importance of each input variable (%) by using **absolute** connection weights, the connection weight approach simply calculates the sum of the contributions of each input neuron using **relative** (or raw) connection weights (Table 6.3).

The main difference between these two methods is therefore the fact that the connection weight approach accounts for counteracting connection weights between input and

output variables, i.e. opposite directions (“+” and “-“ or “-“ and “+”) for incoming and outgoing weights from the hidden neurons. It has to be stated that input variables with larger connection weights represent greater intensities of signal transfer and therefore are more important in the prediction process than variables with smaller weights. Furthermore, negative connection weights represent inhibitory effects on neurons (i.e. reducing the intensity of the incoming signal) and decrease the value of the predicted response, whereas positive connection weights represent excitatory effects on neurons (i.e. increasing the intensity of the incoming signal) and increase the value of the predicted response. Table 6.3 shows the results of the connection weight approach and the Garson’s algorithm for the same NC-S sub-model as used as an example above (i.e. seven inputs, nine hidden neurons, learning rate of 0.2 and momentum of 0.1). When comparing the final rankings, there is clearly some agreement as well as some divergence between these two approaches.

After a thorough literature review (Chapter 2.4), it was decided to skip the Garson’s algorithm in the following as it was generally outperformed in its ability to accurately quantify the importance of a variable in an ANN by the connection weight approach. In addition, NeuroShell 2 offers an internal option to predict the importance of each variable in the trained network. This internal ranking was always compared with the ranking derived from the connection weight approach. However, since NeuroShell 2 does not explain the mechanisms behind its variable ranking tool (the manual just states “The contribution factor is developed from an analysis of the weights of the trained neural network”; Ward Systems Group Inc., 1996), the results have been handled with great caution.

The connection weight approach, which has been proved to be very reliable, is basically a kind of very simple pruning tool as it clearly identifies those variables that only marginally contribute to the prediction of the output. In other words, when aiming for the reduction of inputs during the development process of the models in order to reduce their complexity, the input with the lowest contribution to the network as identified by the connection weight approach was always omitted first. Since this approach worked fine throughout the training of the models, no further specific pruning tools were applied.

Table 6.3 Comparison of the connection weight approach and the Garson’s algorithm for a NC-S network with seven inputs, nine hidden neurons, a learning rate of 0.2 and a momentum of 0.1 (after Olden et al., 2004).

Connection Weight Approach

Garson’s Algorithm

### 6.3 Development of final NC-S, NC-R and NC-SR $g_s$ models

The Tables 6.4, 6.5 and 6.6 summarise the performance of the developed NC-S, NC-R and NC-SR  $g_s$  models with all seven input parameters, respectively. Presented are the results (mean and maximum criteria) for 48 sub-models each per hidden neuron class (from 25 or 20 down to 3), differing in their momentum and learning rate. In other words, each table row represents 48 sub-models. Listed criteria for the evaluation of the performance of models are i) the maximum  $R^2$  value of the relationship between predicted and observed  $g_s$  (the latter representing a subset extracted from the input data), ii) the mean  $R^2$  value ( $n = 48$ ) of the relationship between predicted and observed  $g_s$ , iii) the median and mean scores ( $n = 48$ ) of the sensitivity analysis, iv) the median and mean score ( $n = 48$ ) of the application of the models to a diurnal time course representing a sunny day and vi) the median and mean score ( $n = 48$ ) of the application of the models to a diurnal time course representing a cloudy day.

All models (NC-S, NC-R and NC-SR) performed very well in predicting  $g_s$  rates, with maximum  $R^2$  values of 0.92 (25 HN), 0.93 (13 HN) and 0.88 (23 HN) for the NC-S, NC-R and NC-SR models, respectively. The mean  $R^2$  values representing 48 sub-models of 0.89 (8 HN), 0.91 (9 HN) and 0.87 (9 HN) for the same NC-S, NC-R and NC-SR models, respectively were equally impressive. In general, the maximum and mean  $R^2$  values did not differ substantially between different hidden neuron classes.

## 6. Development of stomatal conductance models

Table 6.4 Performance of ANN-based NC-S  $g_s$  sub-models with seven input parameters. Listed results showing maximum, median and mean ( $\pm 1$  S.D.) values represent 48 sub-models - differing in momentum and learning rate - per hidden neuron class.

The sensitivity analysis and application of models to diurnal time-courses revealed however that high  $R^2$  values of the comparison between predicted and observed  $g_s$  rates were not a guarantee for good results when applying the models to mean observed (sensitivity analysis) or external, previously unseen data (diurnal-time courses) – the latter as opposed to unseen data that had been prior to the training of the ANNs extracted from the input dataset and were used for the comparison between predicted and observed  $g_s$  data.

The results of the sensitivity analyses indicated the best performance with eight, seven and seven hidden neurons for the NC-S, NC-R and NC-SR sub-models, respectively. The application of the sub-models to diurnal time-courses of meteorological and  $O_3$  data proved to be less successful, with most of the NC-S, NC-R and NC-SR sub-models struggling to predict realistic  $g_s$  rates for the sunny day. The cloudy day course was in particular a challenge for the NC-S and NC-SR sub-models, while most NC-R sub-models performed better here.

Interestingly, when considering the combined performance of all evaluation methods described above in order to select three sub-models that would function as the final NC-S, NC-R and NC-SR models, three sub-models with high numbers of hidden neurons performed best: 1) NC-S model with 20 hidden neurons, a learning rate of 0.4 and a momentum of 0.6, 2) NC-R model with 19 hidden neurons, a learning rate of 0.2 and a momentum of 0.6, and 3) NC-SR model with 24 HN hidden neurons, a learning rate of 0.5 and a momentum of 0.7.

The performance of these three models in terms of the direct comparison between predicted and observed  $g_s$  data, the diurnal time course test (sunny and cloudy day) and the sensitivity analysis are shown in Figures 6.5, 6.6 – 6.8 and 6.9, respectively.

The  $R^2$  values of the comparison of predicted and observed  $g_s$  are equally high for all three models. All three models predict slightly lower  $g_s$  rates in direct comparison with observed  $g_s$  rates.

Figure 6.5 Predicted versus observed  $g_s$  for the NC-S (a), NC-R (b) and NC-SR (c) models with 7 input parameters and 20, 19 and 24 hidden neurons, respectively. The observed data represent 20 % of measured input dataset randomly extracted from input dataset prior to training of ANNs.

The application of the three models to diurnal time courses of a sunny and a cloudy day (Figures 6.6 – 6.8) reveal the general ability of all models to quickly react to a change in PAR and air temperature over the course of a day. The same was true for the relationship between  $g_s$  and VPD, which was closely correlated to the air temperature and is not shown here. In terms of the sunny day, all models however showed some scattering in the morning hours. In general, the NC-R model predicted the lowest, the NC-S model the highest rates of  $g_s$ .

Figure 6.6 Diurnal time-course of modelled  $g_s$  using NC-S model with 7 inputs and 20 hidden neurons on a sunny (08.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR.

Figure 6.7 Diurnal time-course of modelled  $g_s$  using NC-R model with 7 inputs and 19 hidden neurons on a sunny (07.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR.

Figure 6.8 Diurnal timecourse of modelled  $g_s$  using NC-SR model with 7 inputs and 24 hidden neurons on a sunny (07.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR.

The sensitivity analyses revealed in general physiologically sensible and expected relationships between predicted  $g_s$  of all three models and air temperature, VPD and PAR (Figure 6.9 a - c). Precisely,  $g_s$  increases with increasing air temperature until approx. 30 °C, above which the curves shown in Figure 6.9 slowly reach a plateau, and decreases with increasing VPD from approximately 0.5 kPa upwards until reaching constant minimum conditions above approximately 2.5 kPa. The dependency of  $g_s$  on PAR is slightly unexpected, because it suggests an increase in  $g_s$  with increasing PAR until only approximately 500 to 750  $\mu\text{mol m}^{-2} \text{s}^{-1}$ , where a low maximum of approx. 300 to 400  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  is predicted with all models (lowest rate for NC-S model). This indicates that when keeping all other input parameters at their mean, no light-saturated rates for  $g_s$  could be predicted.

The exposure time effect curve (Figure 6.9 d) showed a decrease in  $g_s$  with increasing exposure time for the NC-S and NC-SR model, but failed to do so for the NC-R model. The relationship between  $\text{O}_3$  concentration and  $g_s$  was meaningless (Figure 6.9 e), indicating that this parameter was not contributing to the prediction of  $g_s$ .

## 6. Development of stomatal conductance models

Figure 6.9 Sensitivity analysis of the NC-S, NC-R and NC-SR  $g_s$  models with seven inputs and 20, 19 and 24 hidden neurons, respectively. Shown are relationships between predicted  $g_s$  and the entire data range of the parameters air temperature (a), VPD (b), PAR (c), exposure time (d), O<sub>3</sub> concentration (e), AOT40 of exposure time (f) and AOT40 of last 12 days (g). For each graph, all other six input parameters were kept at their overall mean.

Unexpectedly, the NC-SR model predicted an increase in the  $g_s$  rate with increasing AOT40 of exposure time, while this effect was much less pronounced for the NC-S and NC-R models (Figure 6.9 f). The relationship between  $g_s$  and the AOT40 of the last 12 days was less clear, with a slight trend of a decreasing  $g_s$  with increasing AOT40 (Figure 6.9 g).

The analysis of the contribution of each input parameter in predicting  $g_s$  with the ANN-based NC-S, NC-R and NC-SR  $g_s$  models are shown in Table 6.7. This analysis gave varying results depending on which model was tested and whether the connection weights approach or the internal weighting tool of the ANN software NeuroShell was used. Since the former approach is well established and the NeuroShell manual does not explain how the latter approach actually works, it was decided to put more weight in the outcome of the connection weights approach. It showed in general a strong contribution of air temperature, as well as – to a slightly lesser extent - VPD and the AOT40 of the exposure time. In contrast and in agreement with the NeuroShell weighting tool,  $O_3$  concentration was exposed as having in general little influence on the prediction of  $g_s$ , as well as the AOT40 of the last 12 days. This finding corresponded well with the results of the sensitivity analysis, which showed indifferent effect-curves for these two parameters.

Table 6.7 Ranking of input parameters describing their contribution to the prediction of  $g_s$  with the NC-S, NC-R and NC-SR model. Shown are the results of the connection weights approach and the internal weighting tool of the ANN software NeuroShell.

	Ranking connection weights			Ranking NeuroShell 2		
	NC-S	NC-R	NC-SR	NC-S	NC-R	NC-SR
<b>Exposure time</b>	4	3	2	5	6	2
<b>Air temperature</b>	1	1	3	1	2	3
<b>PAR</b>	6	6	7	4	4	5
<b>VPD</b>	3	4	1	3	1	7
<b><math>O_3</math> concentration</b>	5	7	4	7	7	6
<b>AOT40 exp. time</b>	2	2	5	2	5	1
<b>AOT40 12 days</b>	7	5	6	6	3	4

Based on these result, which were comparable to a simple pruning process, the parameters  $O_3$  concentration and AOT40 of last 12 days were excluded and all three models were further developed with only five input parameters, since the main aim was to develop simple models, i.e. models with the lowest amount of hidden neurons and input parameters that could still predict the complex relationship between  $g_s$  and available input parameters. Although PAR did not contribute a lot to the prediction of  $g_s$  either, it was thought to be a key environmental variable driving  $g_s$  and was therefore not considered for exclusion.

Figure 6.10 Predicted versus observed  $g_s$  for the NC-S (a), NC-R (b) and NC-SR (c) models with 5 input parameters and 18, 19 and 19 hidden neurons, respectively. The observed data represent 20 % of the measured data randomly extracted from the total dataset prior to the training of ANNs.

The same procedures as described above for the models with seven input parameters were applied in finding the best NC-S, NC-R and NC-SR models out of the vast pool

of available sub-models differing in number of hidden neurons, learning rate and momentum. This resulted in the final “five input models” with 18, 19 and 19 hidden neurons, learning rates of 0.2, 0.05 and 0.4 and momentums of 0.6, 0.7 and 0.5 for the NC-S, NC-R and NC-SR models, respectively.

The predictive performance of the final “five input models” did not drop substantially in comparison with the initial “seven input models” (from  $R^2$  values of 0.90 to 0.89, 0.92 to 0.89 and 0.87 to 0.79 for the NC-S, NC-R and NC-SR model, respectively; Figures 6.5 and 6.10). The omission of the two parameters listed above was therefore believed to be justifiable and indeed desirable, since it led to simpler but equally meaningful models.

Figure 6.11 Diurnal time-course of modelled  $g_s$  using the NC-S model with five inputs and 18 hidden neurons on a sunny (08.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR. For reasons of comparison, the time curves of  $g_s$  of a NC-R clover clone measured on these days are also shown.

The application of the selected final models to diurnal time courses of a sunny and a cloudy day is depicted in Figures 6.11 to 6.13. All three models performed reasonably well in predicting the diurnal time course of the cloudy day, demonstrated by their ability to react to changes in PAR and temperature over the course of the day. Regarding the sunny day, all three models performed well in the afternoon, but showed in relation to the prevailing weather unexpected high rates of  $g_s$  in the morning hours. However, the also presented measured  $g_s$  rates (though from the contrasting clone – see Chapter 6.2.3) showed similar scatter in the morning hours, i.e. the models probably only reflected the unstable relationship between  $g_s$  and climate variables that is contained in the input dataset the ANNs were trained with.

Figure 6.12 Diurnal time-course of modelled  $g_s$  using the NC-R model with five inputs and 19 hidden neurons on a sunny (07.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR. For reasons of comparison, a time curve of  $g_s$  of the NC-R clover clone measured on that day is also shown.

Figure 6.13 Diurnal time-course of modelled  $g_s$  using the NC-SR model with five inputs and 19 hidden neurons on a sunny (08.08.98, top) and cloudy day (14.08.00, bottom) in comparison with measured air temperature and PAR. For reasons of comparison, a time curve of  $g_s$  of the NC-R clover clone measured on that day is also shown.

Furthermore, the diurnal time courses of  $g_s$  indicate the general difficulties of the models in predicting  $g_s$  for low light or indeed night-time conditions - all  $g_s$  curves for instance show a substantial increase after the sunset on the sunny day. This is mainly a problem linked with the limited ability of ANNs to extrapolate and the fact that the input dataset only included very few low-light or night-time  $g_s$  measurements.

Since the night-time conditions have to be accounted for when calculating  $O_3$  fluxes for entire 28 day clover growing periods, an assumption for low light and night-time  $g_s$  rates had to be made. It was therefore decided to presume a constant clone-specific rate of  $g_s$  for  $PAR < 50 \mu\text{mol m}^{-2} \text{s}^{-1}$  and  $50 \mu\text{mol m}^{-2} \text{s}^{-1} < PAR < 100 \mu\text{mol m}^{-2} \text{s}^{-1}$ , derived from the mean of the above mentioned measurements carried out in emerging

or full darkness (for the NC-SR model the mean of the combined measurements of both clones was calculated). These rates are listed in Table 6.8.

Table 6.8 Assumed constant low-light and night-time  $g_s$  rates ( $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ) for the NC-S, NC-R and NC-SR models derived from  $g_s$  measurements on both clover clones for  $\text{PAR} < 50 \mu\text{mol m}^{-2} \text{s}^{-1}$  and  $50 \mu\text{mol m}^{-2} \text{s}^{-1} < \text{PAR} < 100 \mu\text{mol m}^{-2} \text{s}^{-1}$ . The value for the NC-SR model is based on the pooled  $g_s$  measurements of both clones.

	$g_{\text{snight}}$ ( $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ) for $\text{PAR} < 50 \mu\text{mol m}^{-2} \text{s}^{-1}$	$g_{\text{slowlight}}$ ( $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$ ) for $50 \mu\text{mol m}^{-2} \text{s}^{-1} < \text{PAR}$ $< 100 \mu\text{mol m}^{-2} \text{s}^{-1}$
NC-S model	110	39
NC-R model	52	17
NC-SR model	89	33

As for the “seven input models”, the sensitivity analysis of the final three “five input models” revealed in general physiologically sensible and expected relationships between predicted  $g_s$  and air temperature and VPD (Figure 6.14 a - c). Again, the PAR effect curves reached their low maximum of 200 to 400  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  early at 500 to 750  $\mu\text{mol m}^{-2} \text{s}^{-1}$  PAR. The relationships between  $g_s$  and exposure time as well as AOT40 of the exposure time were less stable, but there was in general the trend that  $g_s$  decreased from approximately day 70 of exposure and increased with AOT40 of the exposure time until approximately 3500 ppb.hrs, after which this increase slowed down.

## 6. Development of stomatal conductance models

Figure 6.14 Sensitivity analysis of the NC-S, NC-R and NC-SR  $g_s$  models with five inputs and 18, 19 and 19 hidden neurons, respectively. Shown are relationships between predicted  $g_s$  and the entire data range of the parameters air temperature (a), VPD (b), PAR (c), exposure time (d) and AOT40 of exposure time (e). For each graph, all other four input parameters were kept at their overall mean.

The analysis of the contribution of each input parameter in predicting  $g_s$  with the ANN-based NC-S, NC-R and NC-SR  $g_s$  models are shown in Table 6.9. It gave again differing results depending on to the applied approach. The connection weights approach was believed to give the more reliable and realistic information (see above). It showed in general the strong contribution of air temperature and VPD as well as the low contribution of PAR in predicting  $g_s$ .

Table 6.9 Ranking of input parameters describing their contribution to the prediction of  $g_s$  with the NC-S, NC-R and NC-SR model. Shown are the results of the connection weights approach and the internal weighting tool of the ANN software NeuroShell.

	Ranking			Ranking		
	connection weights			NeuroShell 2		
	NC-S	NC-R	NC-SR	NC-S	NC-R	NC-SR
<b>Exposure time</b>	4	4	2	2	5	3
<b>Air temperature</b>	1	2	3	5	3	1
<b>PAR</b>	5	3	5	4	2	4
<b>VPD</b>	3	1	1	3	1	2
<b>AOT40 exp. time</b>	2	5	4	1	4	5

Based on the analysis of further exclusion of input parameters which all led to a substantially lower performance of the models in predicting  $g_s$  (data not shown), it was decided that the models with the five input parameters air temperature, VPD, PAR, exposure time and AOT40 of exposure time were the best choice for predicting  $O_3$  fluxes to white clover. Accordingly, when in the following talking of the NC-S, NC-R or NC-SR model, this is always referring to the models with five input parameters described above.

## 7 Application of stomatal conductance and flux models

### 7.1 Application of $g_s$ models to measured time-series data

The final three ANN-based  $g_s$  models were applied to datasets comprising of the main meteorological parameters and the  $O_3$  concentration. These datasets covered five years of growing seasons of five months each at three experimental sites. Due to the vast amount of predicted  $g_s$  data, the following figures of seasonal courses of  $g_s$  rates are shown exemplary for all other growing seasons, years, sites and  $g_s$  models.

Figure 7.1 shows the time-courses of the air temperature, VPD, global radiation and predicted  $g_s$  of the sensitive clover clone using the NC-S model at the site Trier-University during growing periods 2 to 4 in 1997. Low  $g_s$  rates (here expressed as  $g_s$  to  $O_3$ ) were predicted for hot and dry weather periods characterised by high VPD rates (e.g. 7<sup>th</sup> to 19<sup>th</sup> of August) despite the fact that these periods also showed the highest reported PAR values. The model predicted maximum rates of  $g_s$  of up to 420 mmol  $O_3$  m<sup>-2</sup> s<sup>-1</sup> (i.e. approximately 690 mmol H<sub>2</sub>O m<sup>-2</sup> s<sup>-1</sup>) for fairly hot but humid weather conditions, for example on August 2<sup>nd</sup> and 3<sup>rd</sup>. In contrast, the cold spell in late June with daily maximum temperatures of 15 to 17 °C led to relatively low  $g_s$  rates, indicating the overall strong dependence of the predicted  $g_s$  on air temperature.

When comparing the performance of the three different models applied to growing period 4 in 1997 at the site Trier-University (Figure 7.2), the differences in the range of predicted  $g_s$  become clear. While all three models react to the period of high VPD at the beginning of growing period 4 with reduced  $g_s$  - reflecting the closure of stomata to prevent excessive transpirational loss -, the predicted rates of  $g_s$  are always higher for the NC-S clone in relation to those of the NC-R clone. This is valid during dry and hot (beginning of August 1997) as well as during humid and cooler (end of August 1997) weather periods. The  $g_s$  rates predicted with the NC-SR model are in general closer to the rates predicted with the NC-S rather than the NC-R model.

Figure 7.1 Seasonal time-courses (hourly means) of air temperature, VPD, global radiation and predicted  $g_s$  of the sensitive clover clone using the NC-S model. Shown are the central growing periods 2 to 4 at the site Trier-University in 1997.

Figure 7.2 Seasonal time-courses (hourly means) of air temperature, VPD, global radiation and predicted  $g_s$  of the NC-S, NC-R and a hypothetical “intermediate” clover clone using the NC-S, NC-R and NC-SR model, respectively. Shown is growing period 4 at the site Trier-Univ. 1997.

All three models also proved to be able to account for various climate conditions, represented in Figure 7.3 by the three experimental sites. For instance, during the hot and dry weather period at the beginning of August, the VPD was much lower in Deuselbach as compared to the two other sites, resulting in higher  $g_s$  rates predicted for the NC-S clone in Deuselbach. The less extreme and lower range of climate conditions recorded in Deuselbach during growing period 4 in 1997 resulted in general in a more even curve of predicted  $g_s$  as compared to the other sites.

Figure 7.4 presents the 28-days average  $g_s$  rates for all growing periods of all years at each site, calculated with the NC-S, NC-R and NC-SR models. It is obvious that on average the NC-R model always predicted the lowest  $g_s$  rates, indicating that the ozone-resistant clover clone seems to have a lower gas exchange than the NC-S clone. In comparison with the two other sites, the highest  $g_s$  rates were in general predicted for Deuselbach, probably due to the usually more humid and therefore less  $g_s$ -limiting weather conditions there. 1997 was the year with the highest average  $g_s$  rates, probably due to long spells of warm **and** humid weather, while the analysis of seasonal variations in  $g_s$  rates does not reveal clear trends: In some years highest average  $g_s$  rates have been predicted for the beginning of the growing season, while in other years the middle or the end of the growing season showed the highest average  $g_s$  rates. This indicates that the prevailing climate clearly dominates the  $g_s$  rate, rather than the phenological stage (expressed in the model as exposure time) of the clover clone plants.

Figure 7.3 Seasonal time-courses (hourly means) of air temperature, VPD, global radiation and predicted  $g_s$  of the ozone-sensitive clover clone using the NC-S model at the sites Trier-City, Trier-University and Deuselbach. Shown is growing period 4 in 1997.

## 7. Application of stomatal conductance and flux models

Figure 7.4 Average  $g_s$  rates predicted for the five growing periods of the years 1997 to 2001 at the sites Trier-City, Trier-University and Deuselbach with help of the ANN-based NC-S, NC-R and NC-SR  $g_s$  models.

## 7.2 Calculation of ozone fluxes

O<sub>3</sub> fluxes were calculated according to the methods described in Chapter 3.5. The main drivers of these calculations are the modelled  $g_s$  described in the previous chapter and the O<sub>3</sub> concentration at the canopy height. The flux calculations covered five years of growing seasons of five months each at the three experimental sites, using  $g_s$  rates modelled with the NC-S, NC-R or the NC-SR model. Similar to the presentation of the results in Chapter 7.1, the vast amount of calculated O<sub>3</sub> flux data made it necessary to show figures of time-series of calculated O<sub>3</sub> fluxes exemplary for all growing seasons, years, sites and  $g_s$  models.

Figure 7.5 presents the comparison of seasonal changes of O<sub>3</sub> fluxes calculated with the output of the NC-S, NC-R and NC-SR  $g_s$  models. Since all three graphs represent the same site (Trier-University, 1997), the recognisable differences in AFst0 are all based on the differences in  $g_s$  rates calculated with different  $g_s$  models. Accordingly, the accumulated O<sub>3</sub> fluxes based on NC-S model predictions are higher than fluxes calculated with the output of the NC-R  $g_s$  model, indicating higher O<sub>3</sub> fluxes into the NC-S than into the NC-R clover clone. There is no obvious relationship between the seasonal course of AOT40 and AFst0.

When comparing O<sub>3</sub> fluxes calculated with the NC-S  $g_s$  model for the three experimental sites (Figure 7.6), substantial differences in AFst0 can be found. These differences are based on the different modelled rates of  $g_s$ , as well as on the differing pollution climate of these three sites. Since Deuselbach in comparison with the two other sites not only recorded the highest average O<sub>3</sub> concentrations but also offered the best conditions for high  $g_s$  rates (see Chapter 7.1), the O<sub>3</sub> fluxes at this site outweigh the fluxes at the sites Trier-University and Trier-City considerably. This is in particular the case during growing period 4 in 1997, where the AFst0 in Deuselbach is higher than the combined AFst0 at the other two sites.

Figure 7.5 Seasonal time-courses of O<sub>3</sub> concentration (daily mean), AOT40, AFst0 and g<sub>s</sub> (all hourly means), the latter predicted with the NC-S, NC-R and NC-SR model. Shown are five 28-days growing periods in 1997 at the site Trier-University.

Figure 7.6 Seasonal time-courses of  $\text{O}_3$  concentration (daily mean), AOT40, AFst0 and  $g_s$  predicted with the NC-S model (all hourly means). Shown are five 28-days growing periods in 1997 at the sites Trier-City, Trier-University and Deuselbach.

Figure 7.7 summarizes the flux calculations based on the NC-S model results. Shown are the 28-day accumulated O<sub>3</sub> flux rates calculated with different uptake threshold (0 to 10 nmol m<sup>-2</sup> s<sup>-1</sup>), as well as the 28-day AOT40. As already indicated above, Deuselbach is the site with consistently higher O<sub>3</sub> flux rates than those calculated for the sites Trier-City and Trier-University. The lowest rates of g<sub>s</sub> have been calculated for the Trier-City site. When comparing the AFst0 of different growing seasons, the highest flux rates have been predicted for the year 1997.

Since the AFst0 is hugely dependent on the O<sub>3</sub> concentration, Figure 7.7 indicates a positive relationship between AOT40 and AFst0.

## 7. Application of stomatal conductance and flux models

Figure 7.7 Comparison of 28-day accumulated  $O_3$  flux rates calculated with different uptake threshold (0 to  $10 \text{ nmol m}^{-2} \text{ s}^{-1}$ ) and the 28-day AOT40. The flux rates are based on the NC-S  $g_s$  model. Shown are calculated values for five growing periods of the years 1997 to 2001 at the sites Trier-City, Trier-University and Deuselbach.

## 8 Description and analysis of response parameters

### 8.1 Description and analysis of visible foliar injury

At the end of each 28-day growth period (GP) prior to each harvest, a visible injury assessment was carried out on all 40 clover plants exposed at each site according to the standardised injury scoring system described in detail in Chapter 3.3.3. The results of these injury assessments are presented in Figures 8.1 to 8.5, separated according to genotype, growth period, site and year. Shown are the median injury score values, as well as the calculated AOT40 for the respective growth period.

It was decided to join the AOT40 values given in each graph of the Figures 8.1 to 8.5 with a line, thus indicating a **possible** gradient of the potentially phytotoxic O<sub>3</sub> concentration from Trier-City via Trier-University to Deuselbach. As described earlier (cf. Chapter 4.1), the AOT40 values were usually lowest in Trier-City and highest in Deuselbach.

The use of median rather than mean values, which was necessary due to the categorical nature of the variables, leads to somewhat similar results with often little difference in the median values for all three sites. The most frequent injury score for the sensitive genotype is 2 (“1 to 5 % of leaves with injury”), and for the resistant genotype 0 (“no symptoms, healthy”).

In general, there were only very few GPs during the five experimental growing seasons where the ozone-sensitive clover clone was assessed to be healthy. This was the case for seven GPs at the site Trier-University, five GPs at the site Trier-City and three GPs in Deuselbach. The low median injury score of 0 for the sensitive clover clones always matched low AOT40 values of usually below 1000 ppb.hrs. In turn, high AOT40 values correlated well with high injury scores of up to 4 (“25 to 90 % of leaves with injury”). This was particularly the case in 1997 and 2001 (Figure 8.1 and 8.5, respectively), the two years with the highest O<sub>3</sub> concentrations of the entire study period. In fact, the O<sub>3</sub> concentrations were high enough in 1997 to also regularly affect the resistant clove clone with median injury scores of up to 3 (“5 to 25 % of leaves with injury”; Deuselbach GP 4).

However, there were, albeit very few, GPs with low median injury scores despite high AOT40 values, as shown for example for Deuselbach, for both clover clones in GP 2 during 1999 (Figure 8.3).

When comparing the median injury scores of the different field sites, it is surprising how uniform the results are. However, there is a general overall trend with higher injury scores at Trier-University and in Deuselbach in comparison to Trier-City. This again correlates well with the lowest AOT40 occurring at the site Trier-City.

In summary, the results clearly show the higher sensitivity of the NC-S genotype to  $O_3$  in comparison to the NC-R genotype. Also, high AOT40 values are often associated with relatively high median injury score values for both genotypes, whereas the median values are only partly able to identify differences between the observed phytotoxic impacts at the three field sites.

## 8. Description and analysis of response parameters

Figure 8.1 Ozone-induced visible foliar injury assessed on both clover clones (20 plants each) at every harvest in 1997 at the field sites Trier-City, Trier-University and Deuselbach, expressed as the median injury class, as well as the calculated AOT40 values for the respective 28-days growth period (N.B. there was no AOT40 value available for first growth period at Trier-University).

Figure 8.2 Ozone-induced visible foliar injury assessed on both clover clones (20 plants each) at every harvest in 1998 at the field sites Trier-City, Trier-University and Deuselbach, expressed as the median injury class, as well as the calculated AOT40 values for the respective 28-days growth period.

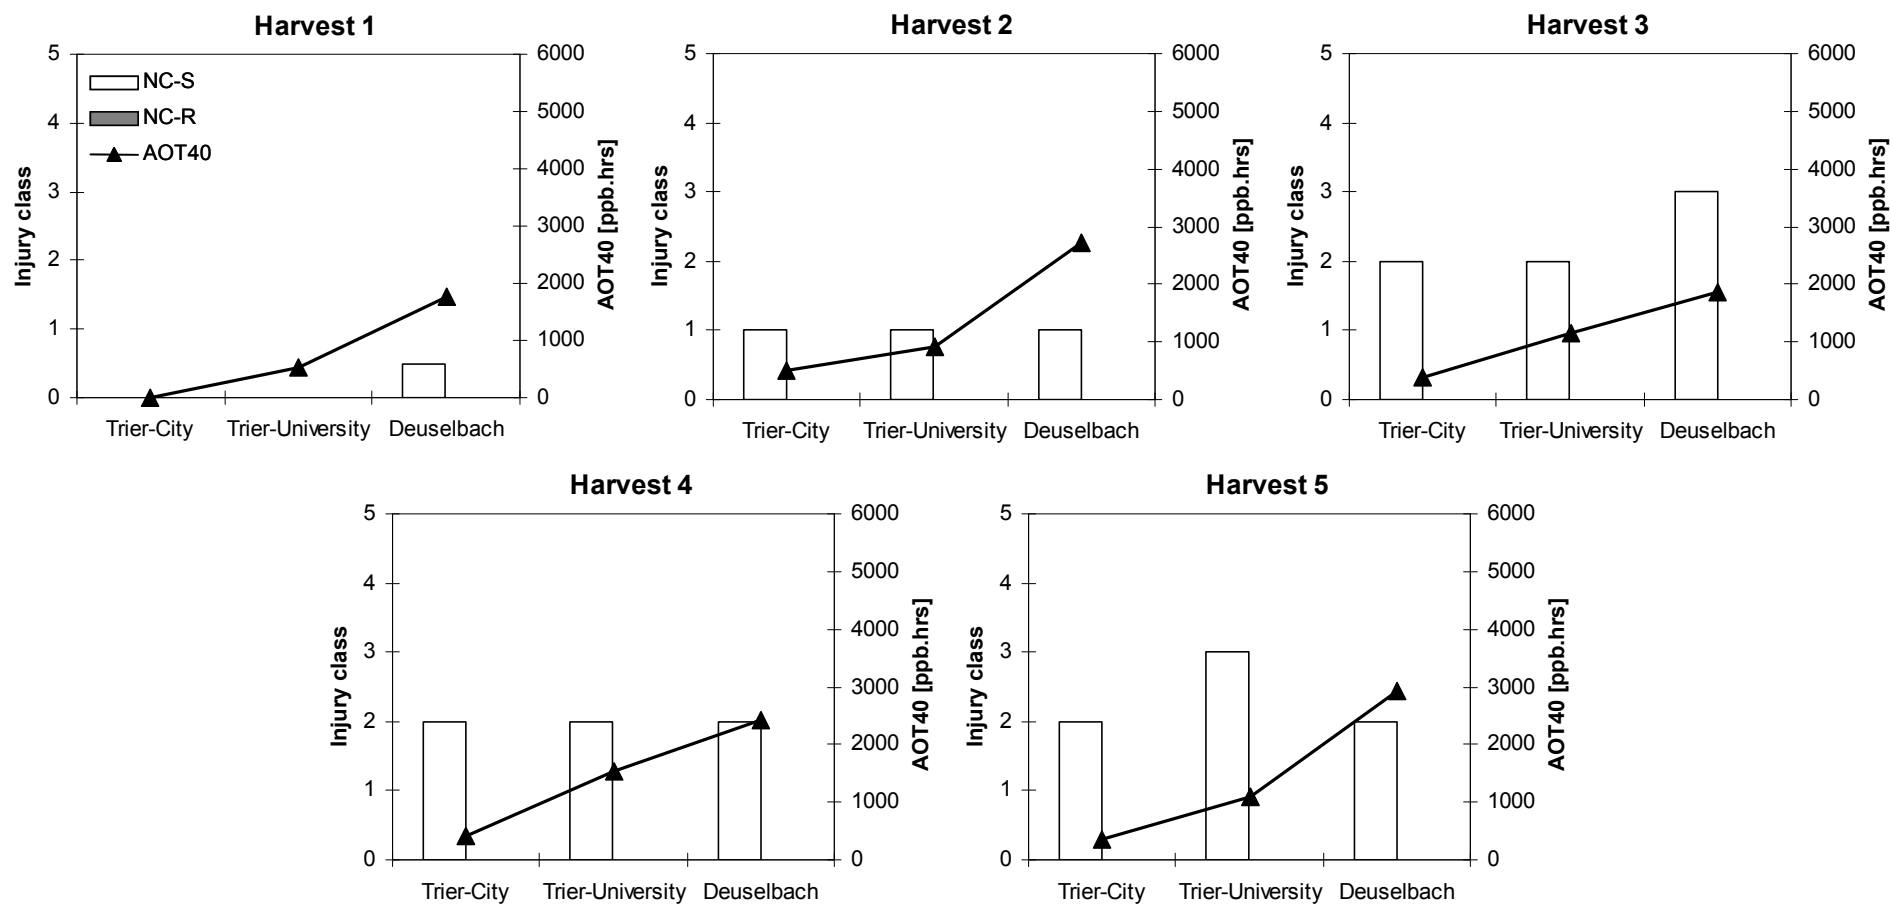

Figure 8.3 Ozone-induced visible foliar injury assessed on both clover clones (20 plants each) at every harvest in 1999 at the field sites Trier-City, Trier-University and Deuselbach, expressed as the median injury class, as well as the calculated AOT40 values for the respective 28-days growth period.

## 8. Description and analysis of response parameters

Figure 8.4 Ozone-induced visible foliar injury assessed on both clover clones (20 plants each at Trier-University; 10 plants each in Trier-City and Deuselbach) at every harvest in 2000 at three field sites, expressed as the median injury class, as well as the calculated AOT40 values for the respective 28-days growth period.

## 8. Description and analysis of response parameters

Figure 8.5 Ozone-induced visible foliar injury assessed on both clover clones (20 plants each at Trier-University; 10 plants of NC-S clone in Trier-City and Deuselbach, no NC-R clones were exposed at these two sites) at every harvest in 2001 at three field sites, expressed as the median injury class, as well as the calculated AOT40 values for the respective 28-days growth period.

## 8.2 Description and analysis of measured clover dry weight

At the end of each 28-days growth period, a destructive harvest of all 40 clover plants per site was carried out, taking away all forage material (including leaves and flowers) above 7cm plant height, plus stolons that had grown over the brim of the 15-litre pots. The harvested material (biomass) was dried and weighed (for details, see Chapter 3.3.3). The results of the dry weight (D.W.) analysis are presented in Figures 8.6 to 8.10, separated according to genotype, growth period, site and year. As an example, harvest 1 is representing the growth of the plants during the 28-day GP 1. Shown are the mean dry weights [g], the ratio between NC-S and NC-R dry weights (the equilibrium value of 1 is marked with a dotted line) as well as the AOT40 [ppb.hrs] and temperature sums [ $^{\circ}\text{C}$  days x 10] for the respective growth period. While the AOT40 provides a means of characterising the pollution climate in terms of potential impact on the growth of the clover plants, the temperature sum is believed to be the main driver defining the impact of the prevailing climate on the growth of the plants.

For all years, sites and both genotypes the biomass increases from Harvest 1 to Harvest 3, with a maximum mean of between 80 to 110 g D.W. being reached depending on the year, before starting to decrease from Harvest 3 to Harvest 5. This decrease can be attributed primarily to the commencing senescence after three months of exposure (the plants are at this stage already four months old, if the first 28-day establishing period in the greenhouse is also taken into account), as well as to the changing weather, i.e. the approaching end of summer with associated reduction in sunshine hours. In fact, a clear drop in temperature sum from GP 4 to GP 5 was detected for all years at all sites (cf. Figure 8.6).

A less uniform picture can be seen when comparing the biomass harvested at the three different field sites. There is however a general trend that the biomass was usually lowest in Deuselbach at Harvest 1, while the plants seem to have been able to adapt to the colder, windier and wetter climate in Deuselbach from GP2 on, after which the biomass was often as high or even higher as the ones reported from Trier-City or/and Trier-University. This was the case despite the usually higher AOT40 values calculated for Deuselbach than for the two other sites, which gives an indication that the absolute biomass did not seem to have been influenced by the prevailing O<sub>3</sub> pollution climate.

## 8. Description and analysis of response parameters

Figure 8.6 Mean biomass [g DW, + 1 S.D.] of NC-S and NC-R white clover clone plants ( $n = 20$  for each clone) exposed to ambient air for 28-days. Shown are the results for Harvest 1 to 5 at the sites Trier-City, Trier-University and Deuselbach in 1997, as well as calculated AOT40 values (no AOT40 value available for first growth period at Trier-University) and temperature sums (baseline = 0°C) for the respective growth period. Bottom right graph: Ratio of biomass of NC-S and NC-R clone (S/R-ratio) of all five harvests at each site (dotted line = equilibrium value of 1).

Figure 8.7 Mean biomass [g DW, + 1 S.D.] of NC-S and NC-R white clover clone plants ( $n = 20$  for each clone) exposed to ambient air for 28-days. Shown are the results of Harvest 1 to 5 at the sites Trier-City, Trier-University and Deuselbach in 1998, as well as calculated AOT40 values and temperature sums (baseline = 0°C) for the respective growth period. Bottom right graph: Ratio of biomass of NC-S and NC-R clone (S/R-ratio) of all five harvests at each site (dotted line = equilibrium value of 1).

## 8. Description and analysis of response parameters

Figure 8.8 Mean biomass [g DW, + 1 S.D.] of NC-S and NC-R white clover clone plants ( $n = 20$  for each clone) exposed to ambient air for 28-days. Shown are the results of Harvest 1 to 5 at the sites Trier-City, Trier-University and Deuselbach in 1999, as well as calculated AOT40 values and temperature sums (baseline = 0°C) for the respective growth period. Bottom right graph: Ratio of biomass of NC-S and NC-R clone (S/R-ratio) of all five harvests at each site (dotted line = equilibrium value of 1).

## 8. Description and analysis of response parameters

Figure 8.9 Mean biomass [g DW, + 1 S.D.] of NC-S and NC-R white clover clone plants ( $n = 20$  for each clone at Trier-University;  $n = 10$  for each clone in Trier-City and Deuselbach) exposed to ambient air for 28-days. Shown are the results of Harvest 1 to 5 at the sites Trier-City, Trier-University and Deuselbach in 2000, as well as calculated AOT40 values and temperature sums (baseline = 0°C) for the respective growth period. Bottom right graph: Ratio of biomass of NC-S and NC-R clone (S/R-ratio) of all five harvests at each site (dotted line = equilibrium value of 1).

## 8. Description and analysis of response parameters

Figure 8.10 Mean biomass [g DW, + 1 S.D.] of NC-S and NC-R white clover clone plants ( $n = 20$  for each clone at Trier-University;  $n = 10$  for NC-S clone in Trier-City and Deuselbach, no NC-R clones were exposed at these two sites) exposed to ambient air for 28-days. Shown are the results of Harvest 1 to 5 at the sites Trier-City, Trier-University and Deuselbach in 2001, as well as calculated AOT40 values and temperature sums (baseline = 0°C) for the respective growth period. Bottom right graph: Ratio of biomass of NC-S and NC-R clone (S/R-ratio) of all five harvests at Trier-University (dotted line = equilibrium value of 1).

The ozone-sensitive NC-S clone would have been expected to grow less well in relation to the ozone-resistant NC-R clone in Deuselbach, the high O<sub>3</sub> pollution site, in comparison with the plants exposed to lower O<sub>3</sub> concentrations at the two remaining sites. However, while this effect, expressed in Figure 8.6 to 8.10 as the S/R-ratio (shown in the bottom right graphs), was detected at more than 50 % of the harvests, there were in each year at least two harvests where at one of the sites Trier-City or Trier-University the S/R-ratio was smaller than the one calculated for Deuselbach despite higher AOT40 values occurring at the latter site (e.g. Harvest 3 and 4 in 1997; Figure 8.6).

Also, the cases when the S/R-ratio was clearly below 1 did not necessarily match the higher AOT40 values and *vice versa*, as can be seen for example for Harvest 2 in 1998 (relatively low S/R-ratio despite relatively low AOT40; Figure 8.7) or Harvest 4 in 1997 (relatively high S/R-ratio despite relatively high AOT40; Figure 8.6). So while in general the NC-S clone did produce less biomass as can be proved by the S/R-ratio being mostly below 1, there is no obvious correlation with the AOT40 of the respective GPs.

In conclusion, when comparing the mean biomass of all harvests for all sites for different years (Figure 8.11), it is obvious that the NC-R clone always (apart from in Deuselbach in 1997) produced more biomass than the NC-S clone. However, the differences in biomass between the NC-S and the NC-R clone did not differ significantly between sites despite significant differences in AOT40 values accumulated over the entire time period of each years growing season (Figure 8.11).

When comparing the mean total dry weights of different years (Figure 8.12), it appears that the clover plants produced the most biomass in 1999, the year with the highest total temperature sum. In contrast, the year with the lowest temperature sums, 1998, showed the lowest total biomass at the sites Trier-University and Deuselbach.

Figure 8.11 Mean biomass (g D.W., + 1 S.D.) of NC-S and NC-R clover plants of all five harvests and the corresponding AOT40 of the entire growing season of the years 1997 to 2001, presented for the sites Trier-City, Trier-Uni and Deuselbach ( $n = 100$ , apart from NC-S and NC-R in 2000 and NC-S 2001 at the sites Trier-City and Deuselbach with  $n = 50$ ; no NC-R plants were exposed in Trier-City and Deuselbach in 2001). The AOT40 value for Trier-Uni in 1997 was omitted due to missing data for the first GP.

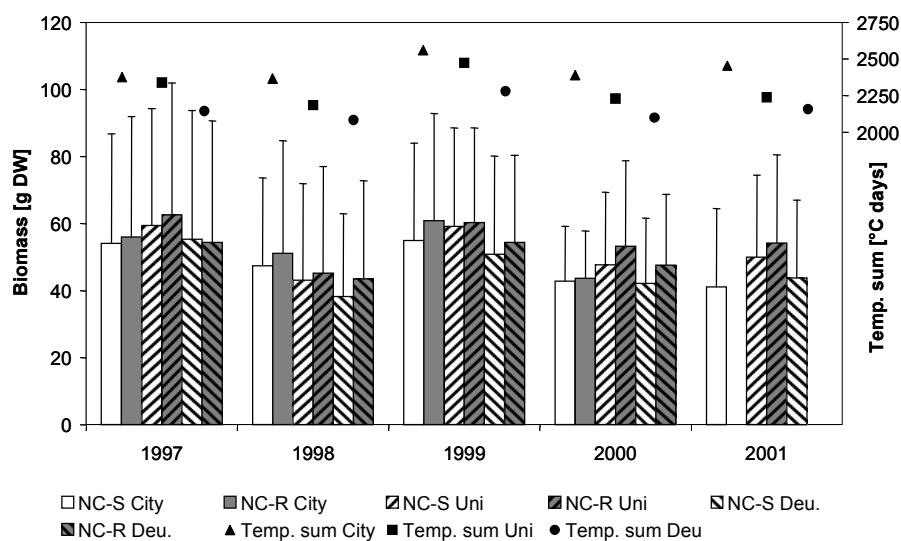

Figure 8.12 Mean biomass (g D.W., + 1 S.D.) of NC-S and NC-R clover plants of all five harvests and the corresponding temperature sums of the entire growing season of the years 1997 to 2001, presented for the sites Trier-City, Trier-Uni and Deuselbach ( $n = 100$ , apart from NC-S and NC-R in 2000 and NC-S in 2001 at the sites Trier-City and Deuselbach with  $n = 50$ ; no NC-R plants were exposed in Trier-City and Deuselbach in 2001).

## 9 Dose-response relationships

The response parameters visible leaf injury and biomass reduction were related to uptake- (AFstX) and concentration-based (AOT40) O<sub>3</sub> indices in order to derive dose-response functions using linear regression analyses.

### 9.1 Response parameter visible leaf injury

Figure 9.1 shows various relationships between the assessed visible leaf injury on the NC-S clover clone, expressed as the median injury class, and the AFst4 based on g<sub>s</sub> predictions using the NC-S g<sub>s</sub> model as well as the AOT40. Presented are dose-response functions for single sites and combined sites.

For the flux-based O<sub>3</sub> index, a threshold of 4 nmol m<sup>-2</sup> s<sup>-1</sup> (AFst4) always resulted in the highest r<sup>2</sup> values for the relationship between foliar injury and O<sub>3</sub> dose. The best performance of the AFst4 was found when relating it to visible leaf injury recorded in Trier-City, the worst to injury recorded at the site Trier-University. When pooling all data, an unsatisfying r<sup>2</sup> value of 0.22 was yielded. In direct comparison, the concentration based O<sub>3</sub> index AOT40 outperformed the flux in explaining the variation in the observed foliar injury assessed in Deuselbach and at the site Trier-University. When pooling all data, the AOT40 also showed a better performance than the AFst4.

It has to be stressed that some of the shown dose-response functions are largely driven by one 1997 record of high O<sub>3</sub> concentration/flux and a related high score of visible leaf injury. When excluding this one data point, the r<sup>2</sup> values drop dramatically for both the AFst4 and AOT40 relationship with visible foliar injury recorded in Deuselbach and in Trier-City (data not shown).

The NC-R clone only showed significant visible leaf injury during some elevated O<sub>3</sub> concentration period, e.g. mainly in 1997. Because of the uniformity of the median injury score – usually 1 for the NC-R clone –, it was impossible to derive any sensible dose-response relationship between visible leaf injury on the NC-R clone and the AOT40 or the AFstX calculated with help of the NC-R g<sub>s</sub> model (data not shown).

Figure 9.1 NC-S clone visible leaf injury expressed as median injury class assessed in 1997 to 2001 at the sites Trier-City, Trier-University and Deuselbach in relation to AFst4 (left column) and AOT40 (right column). Presented dose-response functions are based on linear regression analyses. The visible injury dataset consists of four assessments per site and year.

The same reason has to be mentioned for the failure of the attempt to relate the **first occurrence** of visible injury symptoms - usually reported towards the end of the second week after a harvest - to O<sub>3</sub> uptake or concentration indices. The uniformity of the median score values made it impossible to reveal clear dose-response functions.

## 9.2 Response parameter biomass

Figure 9.2 Relationship between NC-S/NC-R clone biomass ratio and predicted accumulated flux with the NC-S (left column) and the NC-SR (right column) g<sub>s</sub> model using no flux threshold (AFst0) for all five exposure years 1997 to 2001 and all three sites Trier-City, Trier-University and Deuselbach. No NC-S/NC-R biomass ratios were available for the sites Trier-City and Deuselbach for 2001.

The derived dose-response relationships between NC-S/NC-R biomass ratio and AFstX are shown in Figure 9.2 and 9.3. Although for some sites and years satisfying dose-response relationships could be found (precisely Trier-University 1997 and 2000, see Figure 9.3), the general performance of relating AFstX to the NC-S/NC-R biomass ratio was bad (Figure 9.2).

Figure 9.3 also proves that for those sites and years for which sensible flux-based dose-response functions could be derived, the uptake rates using no uptake threshold (AFst0) always led to the highest  $r^2$  values.

Figure 9.3 Performance of the NC-S flux model in describing relative NC-S clone biomass losses using different flux thresholds from 0 up to 10  $\text{nmol m}^{-2} \text{s}^{-1}$  in the years 1997 and 2000 at the site Trier-University.

The use of the concentration based O<sub>3</sub> index AOT40 revealed similarly poor dose-response functions for single years and sites as can be seen in Figure 9.4, as well as for pooled data from all sites and years (data not shown). No clear relationships between AOT40 and the NC-S/NC-R biomass ratio could be revealed.

Figure 9.4 NC-S/NC-R clover clone biomass ratio in relation to AOT40 for all five exposure years 1997 to 2001 and all three sites Trier-City, Trier-University and Deuselbach. No NC-S/NC-R biomass ratios were available for the sites Trier-City and Deuselbach for 2001.

Figure 9.5 NC-S/NC-R clover clone biomass ratio in relation to ratio of accumulated fluxes without threshold predicted with the NC-S and NC-R model (NC-S AFst0/NC-R AFst0) for all five exposure years 1997 to 2001 and all three sites Trier-City, Trier-University and Deuselbach.

When relating the **ratio** between accumulated fluxes using the NC-S and NC-R model (AFstX NC-S/AFstX NC-R) to the NC-S/NC-R biomass ratio, no clear dose-response relationships could be derived either – neither for single sites nor for the pooled data (Figure 9.5).

In an attempt to overcome the dependence on the badly working NC-S/NC-R biomass ratio, the accumulated fluxes (AFst0) were linked to the **absolute** biomass of the clover clones separately. This would not allow any statements on the relative ozone-sensitivity of the NC-S clone because of the missing control, but could reveal if there was at all a relationship between the absolute biomass of the NC-S clone and the predicted flux using the NC-S  $g_s$  model and between the absolute biomass of the NC-R clone and the predicted flux using the NC-R  $g_s$  model. This analysis resulted in clear positive relationships between AFst0 and AOT40 and the biomass of both clones (Figure 9.6), i.e. the biomass of both clones increased with increasing  $O_3$  flux and accumulated  $O_3$  concentrations.

Figure 9.6 NC-S (a, c) and NC-R (b, d) clover clone biomass (g D.W.) in relation to predicted accumulated flux with the NC-S (a) and the NC-R (b) model using no threshold (AFst0), as well as in relation to AOT40 (c, d) for all five exposure years 1997 to 2001 and all three sites Trier-City, Trier-University and Deuselbach.

## 10 Discussion

### 10.1 Assessment of the ANN derived stomatal conductance models

In this thesis artificial neural networks have been used to develop stomatal conductance ( $g_s$ ) models for white clover, which are driven by the meteorological parameters air temperature, photosynthetic active radiation and vapour pressure deficit, as well as the exposure time and the respective accumulated AOT40. Based on these models,  $O_3$  fluxes to white clover were predicted for 28-day growing periods. The choice to use ANNs for this task was based on their reputation of being able to identify complex non-linear relationships between inter-correlated environmental variables, such as the dependence of  $g_s$  on key climatic parameters, and the variation of this relationship due to phenological changes and prevailing pollution climates (in this instance  $O_3$ ) (Balls, 1996; Mills et al., 2000). Because of this ability, it was hypothesised that ANNs should produce more robust predictions of  $g_s$  in comparison to well-established conductance models of empirical or semi-mechanistic nature.

The ANNs were trained with recorded meteorological as well as  $O_3$  concentration data, which were related to simultaneously occurring rates of  $g_s$  measured for potted plants of white clover clones exposed to ambient air.

Three separate models were developed, one for each clover clone (NC-S and NC-R) plus one combined model for both clones (NC-SR). Out of more than 15,000 sub-models differing in their amount and combination of inputs, number of hidden neurons, momentum as well as learning rate, three models that showed the best performance in predicting  $g_s$  were selected. The objective judgement of the performance of each sub-model was based on i) the comparison between modelled and previously extracted measured rates of  $g_s$ , ii) a sensitivity analysis to show the dependence of the output ( $g_s$ ) on each input parameter, iii) the application of each model to datasets representing diurnal time courses of the prevailing climate on a sunny and a overcast day, and iv) the identification of the contribution of each input in predicting  $g_s$  using the connection weights approach.

Prior to the training process of the ANNs, it was shown that different random separations of the input data into training, test and validation datasets in the constant ratio 60:20:20 did not result in the development of principally differing  $g_s$ -models. The input dataset was therefore believed to be extensive enough to potentially lead to a satisfying prediction of  $g_s$  regardless of the extraction data chosen, which represented 20 % test and 20 % validation data.

In the following training process, trial and error methods were applied in order to identify the optimal number of hidden neurons. This number was varied between the maximum value as given per default by the ANN software (i.e. 25, 20 and 25 hidden neurons for the NC-S, NC-R and NC-SR model, respectively), down to a minimum of three. The aim was to identify the simplest model, i.e. the model with the lowest amount of hidden neurons that could still reveal and learn the complex relationship between  $g_s$  and the available input parameters. However, the models with the best performance never had fewer than 18 hidden neurons. This makes the interpretation of the models trickier, but was clearly necessary to optimise the predictive power of the networks/models. Furthermore, this is also an indication for the relative noisiness of the input datasets.

The ideal setting for learning rate and momentum - both important drivers for the direction and speed of the training - to ensure the development of models with a high predictive performance were identified by varying both parameters within a range of 0.05 to 0.7 also using trial and error. This proved to be time-consuming, but successful. While the learning rate tended to produce the best models with values at the lower end of the range mentioned (e.g. 0.1 or 0.2), the momentum showed best results with values at the higher end of the same range (e.g. 0.6 and 0.7). The latter is another clear sign of the relative noisiness of the input datasets.

The training of the network was initiated with all seven input parameters - i.e. air temperature, VPD, PAR, exposure time,  $O_3$  concentration, AOT40 of last 12 days and AOT40 of the total exposure time up to that specific point of the growing period - that had initially been selected since they were expected to be able to contribute to the prediction of  $g_s$ . In fact, of all models, those with the maximum amount of seven input parameters always resulted in the highest  $R^2$ -values between observed and predicted

$g_s$  of up to 0.93. This does not come as a surprise, since – similar to a regression analysis –  $R^2$ -values usually increase with increasing number of independent variables. The question, however, is to what extent a particular variable can contribute to the explanation of the variation or the prediction of a dependent variable; if this contribution is marginal, then the inclusion of this variable only complicates and slows down the training process of an ANN.

Accordingly, when carrying out a sensitivity analysis for these models, it quickly became clear that the parameters  $O_3$  concentration and AOT40 of last 12 days not only lacked any sensible relationship with  $g_s$ , but also seemed to negatively influence the relationship of some of the other inputs with  $g_s$ . In other words, although these two parameters did not really harm the network development, they contributed little to the models' ability to describe the relationship between model inputs and output.

This visual impression was supported by the results of the connection weights approach (for details, see below), which consistently indicated a low contribution of the parameters  $O_3$  concentration and AOT40 of last 12 days in predicting  $g_s$ .

In fact, when excluding these two parameters from the input dataset due to the results of the sensitivity analysis and connection weights approach (an approach not hugely dissimilar to a simple pruning mechanism), the overall predictive performance of the final models did not substantially decrease (changes from  $R^2$  0.90 to 0.89, 0.92 to 0.89 and 0.87 to 0.79 were found for the NC-S, NC-R and NC-SR model, respectively). This is a clear sign that neither the prevailing  $O_3$  concentration nor the exposure to elevated  $O_3$  concentrations over the course of the last 12 days substantially influenced (either negatively or positively) the gas exchange of both clover clones. The omission of these two parameters was therefore believed to be justifiable and indeed desirable.

The results of the sensitivity analysis of all sub-models - from which the final three models were selected - varied according to the number of hidden neurons, the learning rate and the momentum, but in general led to the expected dependence of  $g_s$  on air temperature, PAR and VPD. This was also the case for the three final NC-S, NC-R and NC-SR models with 18, 19 and 19 hidden neurons, learning rates of 0.2, 0.05 and 0.4 and momentums of 0.6, 0.7 and 0.5 for these models, respectively.

When keeping all other inputs constant at rates representing favourable (average) conditions for gas exchange of these clones,  $g_s$  increased with increasing air temperature until approx. 30 °C, above which the response functions indicated the onset of a more or less constant relationship between temperature and  $g_s$ . The sensitivity analysis suggested that this plateau was reached earlier for the NC-S clone. However, with the available input data, it was not possible to accurately predict above which air temperature  $g_s$  would start to be limited. Similarly, the models could not realistically predict  $g_s$  for temperatures below 12.5 °C, but the sensitivity analysis proposed that the  $g_s$  of the NC-S clone was more sensitive to decreases in temperature than the NC-R clone.

The sensitivity analysis also revealed that  $g_s$  decreased with increasing VPD from approximately 0.5 kPa until reaching constant minimum conditions as VPD exceeds approximately 2.5 kPa. The predicted amplitude between maximum and minimum VPD-driven  $g_s$  was much smaller for the NC-R than for the NC-S clone.

The dependency of  $g_s$  on PAR was somewhat more surprising. While there was a steady increase in  $g_s$  with increasing PAR until approximately 500 to 750  $\mu\text{mol m}^{-2} \text{s}^{-1}$ , indicating early light-saturating conditions, the maximum predicted light-saturated  $g_s$  was with 400 and 200  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  for the NC-S and NC-R clone respectively lower than expected. This unexpected result already indicated the limited contribution of PAR in predicting  $g_s$  for all three models, possibly caused by model input data only representing a limited range of this variable.

It has to be pointed out that at high light-saturated rates of PAR of above 1200  $\mu\text{mol m}^{-2} \text{s}^{-1}$ , the NC-S model predicted a decrease in  $g_s$ . While this behaviour of the model can be attributed to light inhibitory processes,  $g_s$  rates of up to 150  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  for PAR values of 50  $\mu\text{mol m}^{-2} \text{s}^{-1}$  and lower (representing the time from dusk till dawn) suggest that the clover clones did not fully close their stomata during the night. Indeed, when looking at the input data used for training the models, there are various measurements with  $g_s$  values well above 0  $\text{mmol H}_2\text{O m}^{-2} \text{s}^{-1}$  for dusk, dawn or conditions of complete darkness. The fact that the ANNs based models had problems in predicting  $g_s$  for night-time conditions - despite model input data clearly indicating night-time gas exchange - led to the decision to assume a constant clone-specific rate

of  $g_s$  for  $PAR < 100 \mu\text{mol m}^{-2} \text{s}^{-1}$ , derived from the mean of the above mentioned measurements carried out in very low light or full darkness.

The curves of the sensitivity analysis showing the relationship between  $g_s$  and exposure time are noisier, though all three models obviously show a trend towards decreasing  $g_s$  with increasing exposure time from approximately 40 to 60 days after the initial exposure date (transplantation day of plants from greenhouse into the field). In other words, the performance of the clover plants represented by a reduced gas exchange declined towards the end of the growing period, clearly indicating a senescence effect. This effect might have been caused by less favourable climatic conditions from growing period 4 or 5 on (with the onset of autumn), a general phenology-dependent change in the physiology of the clover clone plants, as well as ozone-induced sluggishness of the stomata. The latter is possible given that the plants have at that time already been exposed to ambient  $O_3$  concentrations - sometimes well above 40 ppb - for more than three months. In this respect, exposure time acts rather as a surrogate parameter for phenology and the long-term effects of the pollution climate.

The relationship between the AOT40 of the respective exposure period and  $g_s$  was surprising as it indicated an increase in  $g_s$  with increasing AOT40 values between 1000 and 3000 ppb.hrs. This relationship was found for all three models and represented information given by the input data during the training of the ANNs. It may be explained by the fact that high AOT40 values usually co-occur with high temperature and PAR values, which – as described above – represent favourable gas exchange conditions for the clones used in this thesis.

Finally, it has to be stressed that the sensitivity analysis applied here always represented **average conditions** of all input parameters in respect to the input dataset apart from the one “target parameter” being investigated, which was varied across its entire measuring range. This means that this tool is in general able to reveal the relationship between various input parameters and  $g_s$  for average conditions, but might diverge from this relationship for non-average conditions, e.g. values representing the lower or upper end of the data range of the input parameters. Because of this, the outcome of the sensitivity analysis should be interpreted with great

caution, since it is unable to reveal the relationship between input and output for all possible data combinations, e.g. environmental conditions. Also, ANNs might have learned an inaccurate dependence of  $g_s$  on some of the input parameters for specific climate conditions (leading for example to local minima or maxima) as a result of an internal interpolation process, which may not have been disclosed by the sensitivity analysis carried out in this study.

For this reason, all models were also always applied to two measured diurnal time courses of air temperature, VPD and PAR (and their matching exposure time and its related AOT40 values), i.e. one sunny and one overcast day. As for the sensitivity analysis, this method only represents a certain combination of input parameters at certain points in time, which limits its general ability to present all conditions. However, since this step is seen as a time series test for the ability of the models to predict  $g_s$  for clover clones over the course of several hours, it was thought to be a good indication whether or not the models would be able to predict  $g_s$  and hence  $O_3$  fluxes for entire growing seasons. It potentially would also disclose climatic conditions (combinations of air temperature, VPD and PAR values) the models had not been trained with, i.e. were not learnt from the input dataset.

Unfortunately, since it is not permitted to apply the models to data used for training and since it was necessary to have a complete diurnal dataset for this part of the investigation, the NC-S model had to be applied to a diurnal time course during which  $g_s$  on the NC-R clone was measured, and *vice versa*. Also, the selected overcast day - though not having been included in any model input dataset - only consisted of  $g_s$  data for the NC-R clone, which again complicated the direct comparison when applying the NC-S or NC-SR model. However, since both clones recorded rather similar  $g_s$  diurnal profiles, even if the absolute  $g_s$  values were variable, to changes in climatic conditions, this assessment was judged to be useful, i.e. the diurnal time course of measured  $g_s$  of a NC-R plant still provided valuable information as to the dependence of gas exchange on the prevailing climate when being compared with the modelled  $g_s$  for the same day using the NC-S model, and *vice versa*. More importantly, this method showed whether or not any of the selected models were capable of reproducing the  $g_s$  response to sudden changes in climate, such as an interspersed cloud-cover reducing the PAR.

The results showed that all three models were indeed able to cope with these sudden changes during the cloudy day, though to a lesser extent than experienced during the measuring campaigns, since the models seem to partly level out the distinctive peaks in PAR (as well as  $g_s$ ) recorded at that day. Cloud-covered periods, well recognisable in terms of reduced PAR, are well correlated with reductions in  $g_s$ , which indicated that there was almost no time lag between decreasing PAR and decreasing  $g_s$ . However, in comparison to the measured  $g_s$  of a NC-R clover plant, all three models predicted higher  $g_s$  value.

Interestingly, all three models showed more problems in predicting a diurnal time course of a sunny day with a smooth bell-shaped air temperature and PAR curve throughout the day. All three models performed well during the afternoon of that day, but showed some unexpected over-prediction during the morning hours, which was in particular the case for the NC-S model. The over-prediction of this model before midday was experienced with all NC-S sub-models, indicating that either the respective input dataset contained a higher  $g_s$  for these climatic conditions (possibly due to high relative humidity rates in the early morning hours which interfered with the gas analyser of the measuring device – as can also be seen by the morning scatter of the measured  $g_s$  on that day) or – more realistically – that the model had to deal with climate conditions the ANN was not trained with and hence could not learn. This would be a typical example of an interpolation error.

However, it has to be pointed out that the selected sunny days only represented a certain point in time, i.e. no general conclusions stating that “the NC-S model is unable to cope with sunny conditions during the morning hours” are justified. Indeed, the over-prediction of  $g_s$  during the morning hours could only be found on very few days during the very hot first half of August in 1998, from which period the sunny day investigated here happens to be taken.

In order to shed more light on the black box of the ANNs, i.e. to better understand their internal functioning, the connection weights approach revealed the relative importance of each of the final five input parameters in predicting  $g_s$ . For all three models, the air temperature and VPD played an important role in this prediction, whereas PAR in general was of minor importance, in particular for the NC-S and NC-

SR model. The exposure time only played an important role for the combined model, whereas the AOT40 of the exposure time, rather surprisingly, contributed significantly to the NC-S model. These findings correspond well with the findings of the sensitivity analysis, i.e. the noisier the curve in the sensitivity analysis graphs, the minor the contribution of this particular parameter in predicting  $g_s$ .

The three models had  $R^2$ -values of 0.89 for both the NC-S and NC-R and 0.79 for the combined NC-SR model for the relationship between predicted and observed  $g_s$ . All models showed a slight under-prediction of  $g_s$ , indicated by intercept values of 49, 37 and 58 for the NC-S, NC-R and NC-SR model, respectively. This minor systematic error of all models is considered to only have a minimal impact on the prediction of  $g_s$  over the course of entire growing seasons. It does not influence the analysis of the gas exchange differences between the two clover clones, since all models showed similar slight under-predictions.

In agreement with the ANN input data, the predicted  $g_s$  values for the NC-S clone were in general significantly higher than those for the NC-R clone, highlighting the differences in gas exchange between these two clones. Surprisingly, the combined NC-SR model did not represent intermediate conditions but tended to predict rates of  $g_s$  similar to those calculated by the NC-S model.

## 10.2 Analysis of predicted seasonal ozone fluxes

For the prediction of  $O_3$  fluxes to white clover at three sites in the Trier area, the ANN based  $g_s$ -models were applied to time series data covering 5-month growing seasons of five consecutive years.

The  $g_s$ -models proved to perform well in predicting  $g_s$  rates for daytime conditions over the time course of the 5-month growing seasons. For night time conditions, a clover clone specific constant  $g_s$  rate based on  $g_s$  measurements was assumed. The models were able to account for varying weather conditions during the course of the day and growing season. The time-courses of  $g_s$  revealed the importance of the air temperature and VPD in defining the  $g_s$ . For relatively cold weather periods – often encountered at the beginning or end of the 5-month growing seasons – and the

application of the NC-R model in particular, some surprisingly low  $g_s$  rates were predicted and therefore had to be interpreted with caution. This led to the decision to exclude any  $O_3$  flux measurements during the **first** 28-day growing period of every growing season for the derivation of flux-response relationships.

The  $g_s$ -model application revealed in general most favourable climate conditions for  $g_s$  at the rural site Deuselbach as compared to the two other urban and sub-urban sites. There was no clear trend of a phenology-dependent seasonal variation in  $g_s$ , which indicates the overriding importance of the climate in defining the  $g_s$ .

Due to the consistently low  $g_s$  rates predicted for the NC-R clone, the average and accumulated 5-month  $g_s$  rates were always lower for this clone in comparison to the NC-S clone.

The application of the  $g_s$ -models for the prediction of  $O_3$  fluxes disclosed by far highest seasonal  $O_3$  flux rates - expressed as AFstX - at the site Deuselbach. This finding has to be attributed to the favourable climate conditions at this site, as well as to the higher  $O_3$  concentrations measured there as compared to the sites Trier-City and Trier-University. Although the different models predicted different  $g_s$  rates, it was shown that the dominant cause for these site-dependent variable rates of AFstX was the  $O_3$  concentration rather than the predicted  $g_s$ .

### **10.3 ANNs – a useful tool for developing stomatal conductance models?**

The Chapter 10.1 already indicated some of the main strengths and weaknesses of the ANN based  $g_s$ -models. The results presented in Chapter 7 show that ANNs were in general capable of modelling  $g_s$  and hence pollutant fluxes for white clover, for typical climate conditions of the Trier region. In fact, high  $R^2$ -values of up to 0.93 for the relationship between predicted and observed  $g_s$  achieved for some sub-models are higher than those that tend to be achieved using empirical or semi-mechanistic models for the prediction of  $g_s$  (Emberson et al., 2000; Uddling, 2004; Büker et al., 2007). This would indicate that ANNs are indeed able to learn, interpret and apply knowledge related to  $g_s$  to predict the complex, non-linear relationship between  $g_s$  and micro-meteorological and phenological variables used as input in the models

presented here. It also demonstrates that ANNs are principally insensitive to inter-correlations between different input variables, a skill that was very beneficial for this study since the Spearman's rank-order correlation test (Chapter 5.2) proved strong correlations between some of the input parameters (e.g. VPD and air temperature).

However, these  $R^2$ -values should be interpreted with caution since the validation dataset – though randomly extracted from the input dataset – used for the comparison with the predicted data represents very similar conditions to those under which the models were trained. In other words, the ANNs identified the complex relationship between the five inputs and  $g_s$  based on the information they were provided with; this information comprised 9114 data points representing 23 days and 5224 data points representing 13 days for the NC-S and NC-R model, respectively.

Though the  $g_s$  measuring campaigns were planned according to the overall aim to achieve a dataset with good representation of typical growing conditions during the summer months in the Trier region, there will be climatic conditions the model was not trained for but will be forced to represent. This circumstance discloses one main weakness of ANNs: while they are able to interpolate to overcome small data gaps, ANNs are very sensitive to larger data gaps and have a very limited ability to extrapolate.

For example, in this thesis this necessitated the assumption of a constant night-time  $g_s$  (see Chapter 10.1) and might also have resulted in the slightly unrealistic predictions of  $g_s$  for particular day-time conditions – e.g. air temperatures below those included in the input data that occurred at the start of growing seasons (early May), low PAR values (induced by sudden cloud cover) despite hot and dry summer days etc. - during the growing seasons of the years 1997 to 2001. However, closer analysis of the diurnal time courses of predicted  $g_s$  did not reveal any major divergences from what would have been expected considering the prevailing climatic conditions, a result that is mainly attributed to the comprehensive input dataset (cf. Chapter 5). It is therefore fair to say that the statement “a model can only be as good as is its input” is possibly even more pertinent to ANNs than for any other type of model.

Another important characteristic for consideration when assessing the use of ANNs for model development is their sensibility to a change in the number of hidden neurons, as well as to a change in learning rate or momentum. Only a slight change in any of these three factors might lead to a different model in respect of its predictive ability. While this characteristic ensures that ANNs can reveal and learn even slight dependencies between any involved parameters, it also significantly complicates and slows down the network developing process. So far, time-consuming trial and error is still the best and most common method for the identification of the ideal model, a fact that often does not appeal to potential users of ANNs.

Another worrying feature of ANNs also found in this thesis is the variation of the contribution of input parameters to the prediction of the output. While VPD and air temperature were predominantly the main contributors to the prediction of  $g_s$  for all models developed within this study, all three remaining input parameters strongly varied in their importance during the model development process. This is on the one hand a sign for ANNs being able to trace similar information via different pathways during the training, but on the other hand also shows their susceptibility to follow wrong tracks that might be suggested by the input dataset.

Closely connected with this finding is the concern for a potential over-prediction of an ANN model leading to a bad generalisation, i.e. prediction ability. However, the intrinsic training procedure of the software largely prevents this error by constantly cross-checking the model output with test data that were extracted from the input dataset prior to the start of the training.

Last but not least, the criticism that ANNs are black box models that are difficult to interpret can nowadays partly be compensated via various ANN interpretation methods also used in this thesis. These methods help the user to get a better understanding of how the resulting network had been developed and how the training can be influenced by changing the combination of input parameters, adding or removing hidden neurons as well as varying the learning rate and momentum. Furthermore, there are now techniques available that reveal the impact of single input parameters on the dependent variable. However, in conclusion ANNs are still not as

easy to interpret as for instance empirical models, where an alteration of model inputs lead to an immediate, obvious and comprehensible change in the output.

As a consequence, ANNs are a good choice for developing site- and species-specific  $g_s$ -models provided that the input dataset is comprehensive and of high quality. The developed  $g_s$ -models can easily be applied to datasets representing similar climatic conditions to those the network was trained with. However, as soon as these specific condition boundaries and combinations are crossed, ANNs start to struggle to predict sensible rates of  $g_s$ . This for instance means that the  $g_s$ -model for potted clover clones developed in this thesis according to available physical and pollution climate data recorded in the Trier region may not be applicable in Southern or Northern Europe due to the different climates in these regions.

#### 10.4 Comparison of different $g_s$ models

The multiplicative Jarvis-type  $g_s$ -models (cf. Jarvis, 1976) that have been used in a number of  $O_3$  flux models (perhaps best represented by the  $DO_3SE$  model developed by Emberson et al., 2000) is based on the presumption that an initially defined maximal  $g_s$  is potentially diminished by non-optimal meteorological conditions and phenological stage of the targeted plant. By doing so, this approach suggests that there is a multiplicative, linear and therefore one-dimensional relationship between the  $g_s$  and its driving variables. It has widely been recognised that this assumption is not always realistic but nevertheless provides a reasonably sound approach, especially when applied to large scale, i.e. regional, datasets (cf. Büker et al., 2007). However, from a purely plant physiological point of view, this approach will eventually have to be replaced by more sophisticated methods that take into account the complex dependence of  $g_s$  and gas exchange in general on a set of inter-correlated meteorological and phenological parameters.

Furthermore, one main criticism of this approach has always been the dependence of the predicted actual  $g_s$  on the correct initial definition of the maximum stomatal conductance ( $g_{s,max}$ ). Since this definition is very difficult to make given the limited number of  $g_s$  datasets that are available for different cultivars, species and climate regions which meet the strict criteria that should be met to define this variable, there is

a danger that an unrepresentative maximum  $g_s$  would lead to a systematic over- or under-prediction of  $g_s$  and hence  $O_3$  flux. In other words, the intrinsic problem of this multiplicative algorithm is the direct dependence of the actual  $g_s$  on this one key parameter.

In contrast, the Ball-Woodrow-Berry algorithm first developed in the late 1980's (Ball et al., 1987) and ever since extensively revised and applied (e.g. Leuning et al., 1995; Nikolov et al., 1995; Müller et al., 2005) assumes a direct and close relationship between net photosynthetic rate and  $g_s$  and as such has a more mechanistic approach to predict  $g_s$ . Specifically, it assumes that  $g_s$  is a function of net photosynthetic rate, relative humidity,  $CO_2$ -concentration at the leaf surface and a dimensionless factor  $m$  representing the species-specific composite sensitivity of  $g_s$  to net photosynthetic rate. In comparison with the multiplicative model, this approach is therefore able to account for plant-specific physiological processes by mechanistically coupling  $g_s$  and photosynthesis. The BWB-model is therefore often preferred by biologists/plant physiologists, although Büker et al. (2007) showed that the predictive performance of this model approach generally does not differ substantially from the multiplicative Jarvis-algorithm, at least when being applied to regional datasets, with  $R^2$ -values for the relationship between measured and observed  $g_s$  of up to approximately 0.65 for both models.

One reason for the poorer than expected performance of the photosynthesis-based approach might be the assumption that the relationship between  $g_s$  and net photosynthetic rate is assumed to be of the same intensity throughout the growing season (constant factor  $m$ ). However, several studies (Wohlfahrt et al., 1998; Kosugi et al., 2003; Müller et al., 2005) have shown that the parameter  $m$  might change with leaf age, which means that a decoupling of  $g_s$  and net photosynthetic rate is likely towards the end of the growing season. This phenomenon is rarely accounted for in the published literature.

Furthermore, the high input requirements have frequently been mentioned as an obvious limitation both in terms of input and parameterisation data of the BWB-algorithm (cf. Büker et al., 2007). The main reason for this is that the net photosynthetic rate, a parameter not always readily available, is required as an input

parameter. Accordingly, BWB-type models are often coupled with photosynthesis models (e.g. LEAFC3; Nikolov et al., 1997), which require detailed meteorological (e.g. ambient CO<sub>2</sub> concentration, dew-point temperature) and species-specific plant-physiological input parameters (e.g.  $V_{m25}$ ,  $J_{m25}$ ,  $K_{c25}$ ,  $K_{o25}$ ) often difficult to obtain.

These shortcomings of the multiplicative and photosynthesis-based models were the reason for considering ANNs as a tool for the prediction of  $g_s$  of white clover. However, as shown in the preceding Chapter 10.2, ANNs also have their distinctive disadvantages. Table 10.1 summarises the advantages and disadvantages of all three  $g_s$  modelling techniques.

Table 10.1 Overview of advantages and disadvantages of three main  $g_s$ -model approaches.

	<b>Empirical algorithm (Jarvis approach)</b>	<b>Semi-mechanistic algorithm (BWB approach)</b>	<b>Artificial Neural Networks (approach used here)</b>
<b>Advantages</b>	<ul style="list-style-type: none"> <li>- flexibility to easily include and exclude factors in equation</li> <li>- well established</li> <li>- successfully applied to regional and local datasets</li> </ul>	<ul style="list-style-type: none"> <li>- relates <math>g_s</math> to eco-physiological (<math>P_n</math>) and biochemical factors</li> <li>- well established</li> <li>- successfully applied to regional and local datasets</li> </ul>	<ul style="list-style-type: none"> <li>- ability to reveal complex non-linear relationship between input and <math>g_s</math></li> <li>- insensitivity to inter-correlation of input data</li> <li>- insensitivity to noisy input data</li> </ul>
<b>Disadvantages</b>	<ul style="list-style-type: none"> <li>- assumption of linear relationship between input and <math>g_s</math></li> <li>- assumption of non-correlated input variables</li> <li>- strong dependence of predicted <math>g_s</math> on prescribed <math>g_{max}</math></li> <li>- non-mechanistic nature of approach</li> </ul>	<ul style="list-style-type: none"> <li>- dependence on net photosynthesis (<math>P_n</math>) → must be observed or modelled</li> <li>- assumption that relationship between <math>P_n</math> and <math>g_s</math> stays constant throughout growing season</li> <li>- some required input parameters difficult to derive/obtain (e.g. <math>m</math>)</li> </ul>	<ul style="list-style-type: none"> <li>- limited extrapolation ability</li> <li>- time consuming training process</li> <li>- interpretation of ANNs difficult → black box model</li> <li>- limited acceptance among scientists and potential users</li> </ul>

In conclusion, due to their strengths and weaknesses all three models have their own niche in which they perform best. While the empirical approach has been proved to

perform well on a regional level, both the semi-mechanistic approach and the ANNs are outperforming the empirical approach in predicting  $g_s$  on a site-specific level. ANNs are expected to better predict species- and site-specific  $g_s$  because they clearly outperform the other two approaches in revealing the complex relationship between available input parameters and  $g_s$ , however this comes at a price since the training process of the ANNs is time-consuming and their application is restricted to datasets that match more or less the range of the input data the ANNs were trained with.

### **10.5 Analysis of reported difference in sensitivity of NC-S and NC-R clones to ozone**

The results presented in Chapter 8 clearly show the differing sensitivity of the NC-S and NC-R white clover clone to ambient  $O_3$  exposure. In particular the ozone-induced foliar injury was much higher for the ozone-sensitive in comparison to the ozone-resistant clone. Furthermore, during reasonably warm and dry weather periods, the NC-S clone produced less biomass in relation to the NC-R clone, resulting in NC-S/NC-R ratios of below 1, with a minimum record of 0.73 for the second harvest in Deuselbach in 1998. Not surprisingly, the lowest NC-S/NC-R biomass ratio was reported from Deuselbach, since this is the site with the highest  $O_3$  concentrations and indeed highest predicted  $g_s$ . However, some NC-S/NC-R biomass ratios of up to 1.1 were also recorded in Deuselbach, an elevated wind-exposed site in the Hunsrück mountains, especially during cooler and wetter growing periods, indicating the higher sensitivity of the NC-R clone to unfavourable growing conditions.

These findings indicate that the NC-S clover clone is not only more susceptible to acute visible foliar injury following short-term exposure to elevated  $O_3$  concentrations, but also to long-term (here 28 day growing periods, followed by a harvest)  $O_3$  exposure. This has also been reported from other research groups throughout Europe and North America (e.g. Heagle et al., 1995; Bermejo et al., 2002; Fagnano et al., 2004) and has led to mainly two theories being put forward to try to explain why the NC-S clone is more ozone-sensitive:

- 1) The on average higher  $g_s$  of the NC-S clone leads to higher  $O_3$  fluxes into the plant interior as compared to the NC-R clone, causing more cell damage in the former. As an effect, acute visible injury is more pronounced on the NC-S

clone, while on a longer term its photosynthetic capacity is reduced, resulting in less biomass.

- 2) A lower detoxification potential, expressed for instance as lower concentration rates of antioxidants such as apoplastic ascorbate or glutathione, reduces the ability of the NC-S clone to cope with prevailing pollutant/ O<sub>3</sub> fluxes.

It might well be that there is no single explanation for the increased O<sub>3</sub> sensitivity of the NC-S clone, i.e. a mixture of physiological and biochemical processes may well govern the phytotoxicity of this clone to O<sub>3</sub>.

The gas exchange measurements carried out for this thesis as well as the predictions of  $g_s$  for the course of entire growth periods using the developed ANN-based models indeed suggest that one of the main reasons for the higher susceptibility of the NC-S clone to O<sub>3</sub> might have been its higher  $g_s$  as compared to the NC-R clone: The predicted rate of  $g_s$  was in fact always, i.e. at all sites and for all growing periods during all five exposure years, significantly higher ( $P = 0.000$ ) for the NC-S than for the NC-R clone. Logically, this resulted in significantly higher O<sub>3</sub> fluxes into the NC-S clover plants, which might explain the differences in foliar injury and biomass between the two clones.

Curves depicting the predicted  $g_s$  over the course of an entire growing season show that the NC-S clone is responding to dry weather conditions by limiting its gas exchange through a reduction in the width of the stomata, though to a lower extent than the NC-R clone. The strategy of the NC-S clone seems to be to sustain its photosynthetic activity as long as possible, rather than sufficiently closing the stomata to prevent the influx of pollutants. This behaviour, which probably would not have occurred in white clover growing under field conditions, can be partly explained by the experimental set-up of the clover clone bioindicator system used in this study. The well-maintained water supply of the clover plants (using constantly accessible water reservoirs) helped to minimise a decrease in the leaf water potential, which did not make a complete closure of the stomata necessary to stop water losses through transpiration for hot and dry weather conditions.

This is also a clear sign for the artificial nature of the bioindicator system used, which limits the application of the developed  $g_s$ -models to clover grown under field conditions. For field conditions, a soil water limitation parameter (e.g. soil water potential, soil moisture deficit, soil water content) would have had to be included as an input parameter for the training of the  $g_s$ -model.

Unfortunately, it was not possible (nor within the scope of this thesis) to analyse the concentration of (apoplastic) antioxidants known to be able to scavenge reactive oxygen species formed after an  $O_3$  attack. These biochemicals that define the detoxification potential of plants have been shown to be able to react quickly to  $O_3$  attacks, therefore (partly) compensating potentially harmful doses of pollutants such as  $O_3$  (Castillo et al., 1987; Calzada et al., 2001; Van Hove et al., 2001). However, when directly comparing the levels of apoplastic ascorbate in both white clover clones used in this study, D'Haese et al. (2005) found that in comparison with the NC-R clone the NC-S clone always had higher levels of this antioxidant and concluded that high levels of apoplastic ascorbate do not necessarily induce a higher tolerance of plants to  $O_3$ . This is further support for the suggestion that physiological processes might primarily contribute to the relative ozone-sensitivity of the NC-S clone.

### **10.6 Concentration- vs. flux-based dose-response relationships**

The  $O_3$  exposure- and dose-response relationships developed in this thesis for the sensitive and resistant white clover clones are only partly satisfying. It proved to be very difficult to show sensible relationships between the exposure or the dose of  $O_3$  - expressed either as AOT40 or accumulated modelled fluxes using various thresholds (AFstX), respectively - and the response parameter biomass, whereas the relationship of AOT40 and AFstX with the response parameter visible leaf injury yielded better results.

While a few significant relationships between biomass ratio and AFstX could be demonstrated for specific sites in specific years (e.g. AFst0 at Trier-University in 1997 and 2000), the overall performance was poor. In general, the dose-response relationships implied that the NC-S clone showed an increasingly reduced biomass in relation to the NC-R clone with increasing AFstX, whereas the results suggest the

opposite (increasing NC-S biomass in relation to NC-R biomass with increasing AFstX) for the Deuselbach site. For the Trier-City site, the clover showed no response to increasing AFstX whatsoever. These statements are true for the AFstX predicted with both the NC-S and the NC-SR model. When pooling all data, no clear relationship between dose and NC-S/NC-R biomass ratio could be determined.

Also, it was impossible to identify a general flux threshold that worked best for the derivation of dose-response relationships, there was however a trend that no threshold (AFst0) seemed to perform best.

Interestingly, the best (though usually mediocre or worse in absolute terms) dose-response relationships could in general be shown when relating the NC-S/NC-R biomass ratio to accumulated fluxes at the sub-urban site Trier-University. This might be explained by the fact that the models had also been trained with data recorded at this site, which in turn means that the application to more urban (Trier-City) and rural (Deuselbach) climate conditions has to be treated with caution. However, it might as well be an indication for the clover clone bioindicator system having worked best at this site.

Considering these poor results, other dose parameters were considered, such as the ratio between accumulated fluxes using the NC-S and NC-R model (AFstX NC-S/AFstX NC-R), which did not result in any improvement of the dose-response relationships. When relating the accumulated fluxes to the absolute biomass of the clover clones separately, positive relationships between AFstX and AOT40 and the biomass of both clones were detected. This shows that both clones benefited from the warmer climates experienced during growing periods with high O<sub>3</sub> concentrations rather than suffering from the higher pollutant doses at these times, which is another proof for the limited suitability of the clover clone bioindicator system in Central Europe.

The unsatisfying dose-response relationships using the NC-S/NC-R biomass ratio as response parameter are in agreement with reports from various other Central and Northern European members of the ICP Vegetation programme that have participated in the clover clone bioindicator campaign (personal communication). There is in fact

general agreement that the NC-R clone is less adapted to cold and moist climates than the NC-S clone, leading to lower biomass rates despite being more resistant to O<sub>3</sub>. It therefore has to be judged as a weak if not unsuitable control for the evaluation of O<sub>3</sub> impacts on the NC-S clone. This theory is supported by the results of this thesis, showing that the relationships between flux and NC-S/NC-R biomass ratio are particularly bad for the site Deuselbach, the on average coolest and wettest site included in this study. In contrast, during hot and dry summer periods, the flux-response relationships improved, as can for instance be seen for the years 1997 and 1999 at the site Trier-University. Accordingly, Southern European researchers have shown that the clover bio-indicator system works well under Mediterranean climate conditions (e.g. Bermejo et al., 2002; Fagnano et al., 2004), which is not surprising considering the propagation and establishment of these white clover clones in the subtropical climates of North Carolina, U.S.A. (Heagle et al., 1995). The origin of these clones is hence an indication of their adaptation to hotter and drier climates. However, the usually higher O<sub>3</sub> contractions in Southern Europe might also contribute to the successful application of the clover bioindicator system there, which might in turn indicate that the Northern European O<sub>3</sub> concentrations are not high enough to cause substantial biomass reduction of the NC-S clone.

It was furthermore not possible to show whether the ozone-sensitivity of the NC-S clover clone differed over the course of the growing season, i.e. with phenological stage. The rates of the NC-S/NC-R biomass ratio varied throughout the entire growing season – quite possibly due to the enhanced climate induced variability in the growth of the NC-R clone - and did not allow any conclusions as to the temporal variation in the ozone-sensitivity of the sensitive clove clone.

One further reason for the difficulties in deriving strong relationships between O<sub>3</sub> flux and the NC-S/NC-R biomass ratio might be the fact that the g<sub>s</sub>-models are based on leaf-level g<sub>s</sub> measurements. Although the used leaves for gas exchange measurements (third or fourth from tip of the stolon) were believed to well represent the average gas exchange of the entire plant, a desirable up-scaling procedure from leaf to plant could not be derived due to the lack of LAI data. A first attempt to develop a canopy-flux model for white clover was presented by Harmens et al. (2006) but resulted in direct

comparison with the leaf-level flux model in a lower  $r^2$  value for the dose-response function, which was the reason for turning down this approach here.

In comparison, the relationship of  $O_3$  exposure and  $O_3$  dose with the response parameter visible leaf injury was more satisfying. It could be shown that for all sites there is a positive relationship between 28-day AFstX – with best results for AFst4 – as well as 28-day AOT40 with visible leaf injury assessed at the end of 28-day growing periods. The AOT40 consistently outperformed the AFstX apart from the calculation for the site Trier-City, i.e. the exposure index usually explained more variation in the observed foliar injury than the uptake index. It has to be pointed out that the results of the linear regression (i.e. the  $r^2$ -values) shown in Figure 9.1 are very much driven by one 1997 data point representing very high  $O_3$  concentrations and  $O_3$  fluxes and related high injury scores. When excluding this data point, most regression results deteriorated.

Though the NC-R clone also showed some visible injury during high  $O_3$  concentration periods, no sensible relationship between its median score (usually 0, sometimes 1) and  $O_3$  exposure or dose indices could be developed. Furthermore, the relation between the **first occurrence** of visible injury on both clones – typically assessed during the second week (i.e. on average 12 days) after the last harvest – and  $O_3$  exposure or dose indices did not deliver meaningful results (data not shown) because of the reported injury score, which when pooling the data was too even with median values of usually 1 for the NC-S and 0 for the NC-R clone.

This indicates the problems that occurred in using the response parameter visible leaf injury. First of all, despite working according to a standardised experimental protocol that precisely describes how to perform visible injury assessments, these assessments have to be considered as being somewhat subjective. These assessments were always carried out by the same person (the author of this thesis), which helped to minimise the variation in the recordings. However, some variation in the recorded assessments has to be attributed to the subjective judgement of the assessor, for example at the start of each growing season in May (which was another reason for always excluding the first 28-day growing period from any further analysis).

Another problem of the visible injury assessment is – as already mentioned above - the classification method: Though without doubt practical, its wide and varying range of injury within one class makes a proper analysis difficult. Rather than using a percentage of injured clover leaves, the median (the mean was not acceptable due to the ordinal nature of the data) injury class (from 0 to 5) had to be chosen in this thesis as the response parameter. Unfortunately, this led to very evenly distributed characterisations of the injury, with most injury on the NC-S clone either falling into class 2 (1 to 5 % of leaves injured) or class 3 (5 to 25 % of leaves injured).

In conclusion, these difficulties and shortcomings of the experiment strongly suggest that the reported poor dose-response relationships in respect to the response parameter biomass have to be mainly attributed to the failure of the bioindicator system under these particulate climate conditions rather than to a failure of the developed flux models. This statement is supported by the findings that no clear exposure-response relationship between relative biomass loss and AOT40 could be developed either, further indicating the limited suitability of the used bio-indicator system in quantifying O<sub>3</sub> effects on the growth of pot-grown clover clones or legumes and forbs in general.

However, the relationships between visible leaf injury and O<sub>3</sub> exposure or O<sub>3</sub> dose were more satisfying, which suggests that the clover clones are suitable as bio-indicators for the easy and inexpensive detection of effect of tropospheric O<sub>3</sub> on plants at a particular site.

With the results presented in this thesis, it is very difficult to give a sensible recommendation whether or not dose- rather than exposure-indices are more suitable to predict impacts of tropospheric O<sub>3</sub> on the NC-S and NC-R clones. In terms of biomass losses, a recommendation is indeed very difficult due to the poor results reported above. However, there is a slight trend for a better performance of the dose- rather than the exposure-index in predicting ozone-induced detrimental effects on the biomass production of clover clones; there is in other words certainly no reason why the flux approach should not be considered for this purpose. In contrast, the O<sub>3</sub> exposure index AOT40 seems to be the better choice in explaining and predicting leaf foliar injury of the (potted) white clover clones.

### 10.7 Conclusions and perspectives

The previous chapters showed in detail the advantages and disadvantages of the ANN-based  $g_s$ -models as well as the used clover clone bio-indication system. The overall representativeness and significance of the study has to be judged on these findings.

The scope of this study was to i) test ANNs for their suitability in developing  $g_s$ -models based on climatic, phenological and  $O_3$  pollution data, ii) investigate whether the developed  $g_s$ -models for white clover clones are able to realistically predict  $O_3$  fluxes to these plants, iii) compare the performance of  $O_3$  dose- with  $O_3$  exposure-indices in relation to recorded response parameters, iv) investigate whether or not the higher  $O_3$  sensitivity of the NC-S clone might be related to higher rates of  $g_s$  as compared to the NC-R clone and v) evaluate the used bio-indicator system for its ability in quantifying ozone-induced impacts on two white clover clones and plants in general.

It has been shown that ANNs are indeed a useful tool for developing species-specific  $g_s$ -models for application on a site-specific scale. The application of the  $g_s$ -models specifically developed for an ozone-sensitive and ozone-resistant white clover clone grown under non-limiting water supply is therefore limited to these pot-grown clones and to West European climate conditions similar to those recorded in Trier. It is not possible – and indeed was not within the scope of this study - to apply the models and transfer the findings to field-grown plants, not even to field grown white clover, because of the species-specific nature of the models and the lack of any soil water model input parameters.

With the help of the developed ANN-based  $g_s$ -models, differences in  $O_3$  fluxes between the two clones, different growth stages over the course of a 5-month growing season and different sites in the Trier area could be predicted.

When relating these  $O_3$  flux rates to the response parameters NC-S/NC-R biomass ratio and visible leaf injury, reasonable dose-response functions ( $r^2$  values of up to 0.54) could be developed for the latter, whereas the dose-response functions for the former were very weak ( $r^2$  values of up to 0.21), possibly due to the leaf-level rather than canopy-level  $g_s$ -models developed here and the generally bad performance of the

white clover bioindicator system. The fact that exposure-response functions using AOT40 did not perform better stresses the limited suitability of the response parameter NC-S/NC-R biomass ratio in the Trier region.

A recommendation whether to use dose- or exposure-indices for quantifying O<sub>3</sub> impacts on the growth of clover is therefore difficult. However, the exposure index AOT40 outperformed the dose calculations in revealing and predicting the impact of O<sub>3</sub> on foliar leaf injury.

The  $g_s$  differed significantly between the two clones. The NC-S clone always showed higher rates and therefore higher O<sub>3</sub> fluxes, which might be one reason for its higher ozone-sensitivity as compared to the NC-R clone.

The white clover bio-monitoring system did not work well during relatively cool and wet growth periods, but performed better under warmer and drier weather conditions. The response parameter visible injury led to better dose-response relationships than the response parameter relative biomass loss.

One way how to overcome the reported difficulties in the two clones reacting differently to the prevailing climate would be to develop a clover growth model for each clone based on meteorological parameters. This would help to compensate the overlaying climate effect on the prediction of the NC-S/NC-R biomass ratio, which could then result in better dose-response relationships for the clover clones. Also, a further approach in up-scaling from leaf- to canopy-level fluxes using LAI data could potentially improve the dose-response functions.

Last but not least, repeating the experiment with field-grown clover clones and corresponding measurements of soil water parameters would enable the model to account for varying soil moisture conditions, which potentially would make it possible to transfer the dose-response functions to “naturally-grown” white clover in the field.

# **APPENDIX A**

## **Descriptive statistics of climate data**

Figure A.1 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and O<sub>3</sub> concentration (e) of all growth periods (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach in 1997. In each sub-figure, the far right set of bars represents the mean of all five GPs, i.e. the growing season mean. Wind speed data at the site Trier-University were not available for 1997.

Figure A.2 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and O<sub>3</sub> concentration (e) of all growth periods (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach in 1998. In each sub-figure, the far right set of bars represents the mean of all five GPs, i.e. the growing season mean.

Figure A.3 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and O<sub>3</sub> concentration (e) of all growth periods (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach in 1999. In each sub-figure, the far right set of bars represents the mean of all five GPs, i.e. the growing season mean.

Figure A.4 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and O<sub>3</sub> concentration (e) of all growth periods (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach in 2000. In each sub-figure, the far right set of bars represents the mean of all five GPs, i.e. the growing season mean.

Figure A.5 Mean (+ 1 S.D.) air temperature (a), VPD (b), PAR (c), wind speed (d) and O<sub>3</sub> concentration (e) of all growth periods (GP = 28 days) at the sites Trier-City, Trier-University and Deuselbach in 2001. In each sub-figure, the far right set of bars represents the mean of all five GPs, i.e. the growing season mean.

Table A.1 Mean ( $\pm$  S.E.) and range (maximum and minimum) of air temperature, VPD, PAR, wind speed and O<sub>3</sub> concentration of 1997 growth periods (GP = 28 days) 1 to 5 at the three experimental sites Trier-City, Trier-University and Deuselbach.

## Zusammenfassung

Troposphärisches Ozon ( $O_3$ ) kann zahlreiche negative Effekte bei Pflanzen hervorrufen, wie z.B. sichtbare Blattschäden, Biomass-Einbußen oder verfrühte Seneszens. Die Hintergrundkonzentrationen dieses sekundären Luftschadstoff sind im Laufe der letzten Jahrzehnte stetig gestiegen und eine Umkehr dieses Trends ist vorläufig nicht abzusehen. Aus diesem Grund sind Strategien zur Reduktion der Ozon-Vorläufersubstanzen notwendig, die sich auf den Nachweis von phytotoxischen Wirkungen Ozons stützen können müssen. Aus diesem Grund ist der Einsatz von Bioindikations-Verfahren sehr populär, da er auf einfache, kostengünstige Weise den Einfluss von Luftschadstoffen auf Pflanzen nachweisen kann und damit eine Beurteilung der Luftqualität zulässt.

Während traditionell konzentrationsbasierte Verfahren, wie z.B. der AOT40 (Summe der Ozonkonzentrationen über 40 ppb), mit oben genannten Wirkungsparametern in Beziehung gesetzt wurde, weiß man heute, dass die stomatär aufgenommene Dosis von Luftschadstoffen besser mit den auftretenden Wirkungen in Beziehung gebracht werden kann. Das hat dazu geführt, dass die Nachfrage von Fluss-Modellen, speziell Ozonfluss-Modellen, stetig gestiegen ist. Diese Modelle sind alle von der möglichst exakten Bestimmung bzw. Modellierung der stomatären Leitfähigkeit ( $g_s$ ) abhängig.

In der vorliegenden Arbeit wurde mit Hilfe künstlicher neuronaler Netze (ANNs) ein Modell der stomatären Leitfähigkeit für zwei Weiß-Klee-Klone mit unterschiedlicher Ozon-Sensitivität (*Trifolium repens* L. cv Regal; NC-S (Ozon-sensitiv) und NC-R (Ozon-resistent)) entwickelt. Zuvor wurden die beiden Klee-Klone für ein Ozonwirkungs-Monitoring im Freiland ausgewählt, da sie im Rahmen von Bioindikations-Verfahren erfolgreich in Europa zum Nachweis von Ozon-Schäden an Pflanzen eingesetzt worden waren.

Das Biomonitoring wurde während der Vegetationsperioden der Jahre 1997 bis 2001 an drei Standorten in der Region Trier durchgeführt, die sich durch eine unterschiedliche Verteilung der Ozonkonzentration im Tages- wie auch im Jahresverlauf auszeichnen. Als Wirkungsparameter wurden sichtbare Blattschäden und das Verhältnis der Biomasse zwischen NC-S und NC-R Klon aufgenommen. An beiden Klonen wurden ferner Gaswechsellmessungen durchgeführt, die im Folgenden als Output eines ANN-basierten Modells der stomatären Leitfähigkeit fungierten. Als Input dienten die zeitgleich gemessenen meteorologischen Parameter Lufttemperatur,

Wasserdampfdruck-Defizit (VPD) und photosynthetisch aktive Strahlung (PAR), sowie die Ozonkonzentration. Die Wahl des Modell-Typs fiel auf ANNs, weil sie dafür bekannt sind, komplexe nicht-lineare Zusammenhänge zwischen Eingangs- und Ausgangsparametern aufdecken zu können.

Die Entwicklung und Evaluation des Modells wurde detailliert beschrieben. Das resultierende stomatäre Leitfähigkeitsmodell wurde dann zur Berechnung von Ozonflüssen eingesetzt, die im Anschluss mit den nachgewiesenen Ozon-Wirkungen (Blattschäden, relativer Biomasseverlust) in Verbindung gesetzt wurden.

Das Modell war in der Lage, ein enges Verhältnis zwischen stomatärer Leitfähigkeit und den meteorologischen Eingangsparametern aufzudecken und zu erlernen, anhand dessen im Folgenden Zeitreihen von Klee-Ozonflüsse für alle drei Standorte berechnet wurden. Der Versuch, gute Dosis-Wirkungsbeziehungen zwischen diesen Flüssen und den aufgenommenen Wirkungsparametern zu erzielen, wurde nur zum Teil erreicht. Während die sichtbaren Blattschäden positiv mit den ermittelten Ozonflüssen korrelierten, konnten keine eindeutigen Beziehungen zwischen dem NC-S/NC-R Biomasse-Verhältnis und der modellierten aufgenommenen Ozonflussmenge gefunden werden.

Ein Grund für dieses Ergebnis war u.U. der schlechte Wuchs des NC-R Klons bei kühlen und feuchten Witterungen. Ausserdem könnten die ermittelten Blatt-bezogenen Ozonflussraten nicht repräsentativ für Ozonflüsse in die **ganze** Pflanze gewesen sein.

Ein Nachteil der ANNs ist zudem ihr weitgehendes Unvermögen, extrapolieren zu können, das heisst sie treffen nur gute Vorhersagen für Klimabedingungen, die auch im Trainingsdatensatz enthalten waren. Dementsprechend könnten für einige (extreme) Wetterbedingungen fehlerhafte Ozonflussraten vorhergesagt worden sein, wobei darauf hingewiesen werden muss, dass der Trainingsdatensatz der ANNs ausgesprochen umfangreich war und dieses Problem daher nur selten auftrat.

Der NC-S Klon zeigte eine durchgehend höhere stomatäre Leitfähigkeit, was ein Grund für seine höhere Ozon-Sensitivität sein könnte.

Es muss abschließend darauf hingewiesen werden, dass das Modell mit Daten immer wassergesättigter Kleepflanzen trainiert wurde, d.h. eine Anwendung auf Freilandbedingungen ist nicht möglich.

## Summary

Tropospheric ozone ( $O_3$ ) is known to have various detrimental effects on plants, such as visible leaf injury, reduced growth and premature senescence. Since the background concentrations of this air pollutant are increasing and are expected to further increase in the near future, strategies for the abatement of  $O_3$  are required. These strategies have to be based on evidence of impacts, a fact that has made the use of bio-monitoring methods increasingly popular. While the impacts of  $O_3$  on plants were traditionally related to  $O_3$  exposure metrics, such as the AOT40 index (accumulated exposure over a threshold of 40 ppb), there is now general agreement that these impacts are more closely related to the  $O_3$  dose absorbed through the stomata. This led to an increasing interest in the development of appropriate  $O_3$  flux models, all of which are strongly dependant on the correct estimation of stomatal conductance ( $g_s$ ).

This thesis aimed at developing an artificial neural network (ANN) based  $O_3$  flux model for two white clover clones (*Trifolium repens* L. cv Regal; NC-S (sensitive) and NC-R (resistant)) differing in their sensitivity to  $O_3$ . These clones were selected for this study since they have successfully been used in European bio-monitoring campaigns for the detection of phytotoxic  $O_3$  effects and are well represented in various European grassland communities.

The approach of this study was twofold: Firstly, a bio-monitoring experiment exposing the clover clones to ambient air was carried out during five consecutive growing seasons (1997 to 2001) at three sites in the city centre of Trier, on the premises of the University of Trier and in Deuselbach (Hunsrück), representing urban, suburban and rural climate and pollution conditions, respectively. The response parameters visible leaf injury and biomass ratio between NC-S and NC-R clone were regularly assessed. Furthermore, gas exchange measurements were carried out on both clones in order to obtain information on their rate of  $g_s$  and its dependence on the prevailing climate. Secondly, a  $g_s$  model was developed using the measured  $g_s$  data as output and the corresponding climate and  $O_3$  data as input. ANNs were used for this task because of their ability to reveal, learn and predict highly complex non-linear

relationships between two or more variables, such as the dependence of  $g_s$  on air temperature, vapour pressure deficit (VPD) and photosynthetic active radiation (PAR), as well as on prevailing pollutant concentrations (here:  $O_3$ ). These parameters functioned as input of the ANN-based model, whereas the  $g_s$  was the output. The development of the model was documented in detail and various model evaluation tools were applied. The resulting  $g_s$  model was used as basis for  $O_3$  flux calculations, which were then related to the response parameters visible injury and relative biomass loss assessed at the experimental sites.

The results showed that the ANNs were indeed capable of revealing and learning the complex relationship between  $g_s$  and key meteorological parameters and  $O_3$  concentration indices, with resulting  $r^2$  values for the relationship between measured and modelled  $g_s$  of up to 0.93. The model was able to predict realistic rates of  $g_s$  and hence  $O_3$  fluxes for entire growing seasons provided that the data the model was applied to were within the range of data it was trained with, but when relating these fluxes to the response parameters described above, only weak dose-response relationships could be obtained. This might be an indication for the limited suitability of the white clover bio-monitoring system for Central European climate conditions due to the fact that the NC-R clone proved to be sensitive to cold and wet weather conditions. Furthermore, the leaf level  $O_3$  flux predictions might not be representative for the  $O_3$  uptake of entire plants. Last but not least, it has to be stressed that ANNs have a very limited ability to extrapolate, leading in this case to potentially questionable  $O_3$  flux rates for weather conditions the model was not trained with. However, due to the very comprehensive input dataset, these problems have been restricted to relatively extreme weather conditions (e.g. cold periods at the beginning or end of growing seasons). The ANN approach to develop  $g_s$  models was discussed in relation to multiplicative and net-photosynthesis based  $g_s$  models.

The study also revealed significantly higher  $g_s$ -rates for the NC-S clone, which might be an explanation for its higher ozone-sensitivity as compared to the NC-R clone.

Last but not least, it has to be pointed out that the model was trained with  $g_s$  data of potted, well-watered clover plants and is therefore not applicable to clover growing in the field due to the missing link to soil water conditions.

# Lebenslauf

<b>Name</b>	Patrick Bükér
<b>Adresse</b>	45 Scott Street York YO23 1NR England
<b>Staatsangehörigkeit</b>	Deutsch
<b>Geburtsdatum</b>	24.06.1969
<b>Geburtsort</b>	Herford
<b>Schulbildung</b>	1975-1979 Grundschule Quernheim 1979-1989 Freiherr-vom-Stein Gymnasium Bünde
<b>Studium:</b>	1991-1997 Angewandte Physische Geographie/ Geowissenschaften (Abschluss Diplom- Geograph, Universität Trier) Thema der Diplomarbeit: Einsatz der Bioindikatoren <i>Trifolium repens</i> und <i>Phaseolus vulgaris</i> zum Nachweis ozon- induzierter Blattschäden und Ernteverluste 2001-2003 Promotionsstudium Geographie/ Geowissenschaften, Universität Trier
<b>Beruflicher Werdegang</b>	1997-2002 Wissenschaftlicher Mitarbeiter im FB VI Geographie/Geowissenschaften der Universität Trier, Abteilung Geobotanik 2003 Research Associate, Centre for Ecology and Hydrology (CEH), Bangor, Wales, UK 2003-heute Research Associate, Stockholm Environment Institute (SEI), University of York, York, UK
